Auroral kilometric radiation (AKR) - remotely observing the auroral acceleration region

Morioka+ 2013

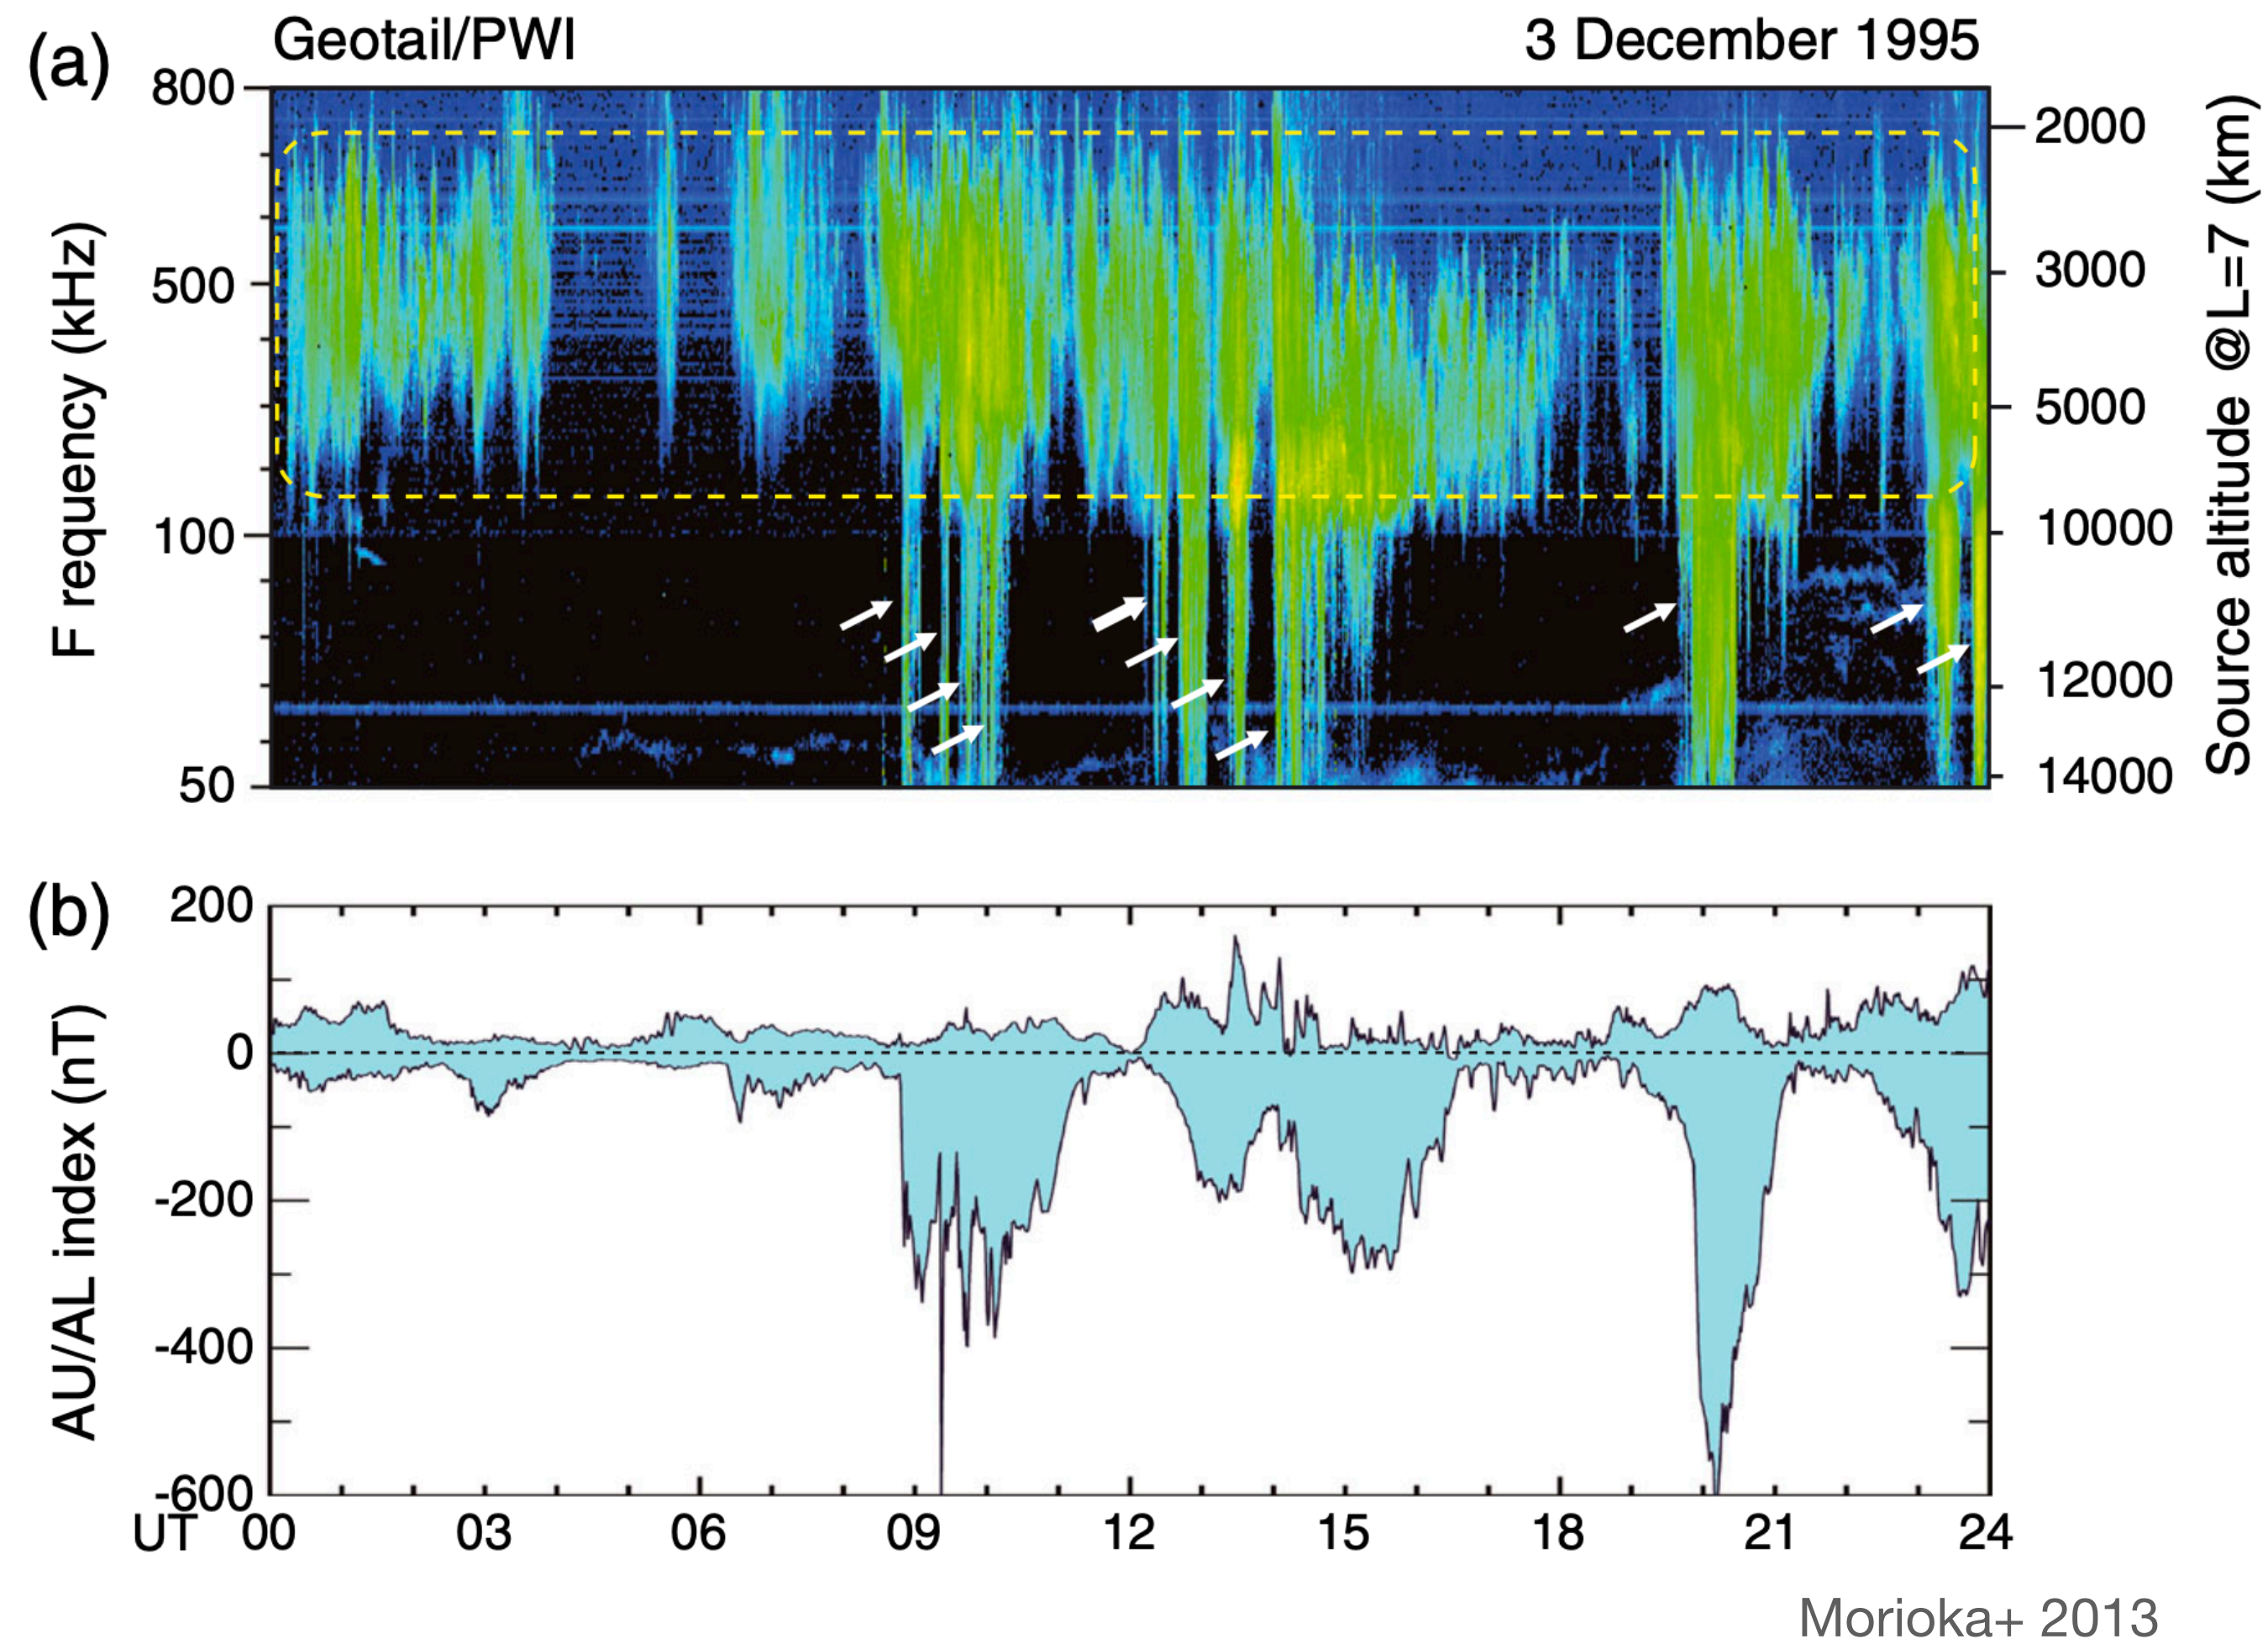

Substorms

Clauer & McPherron+ 1974

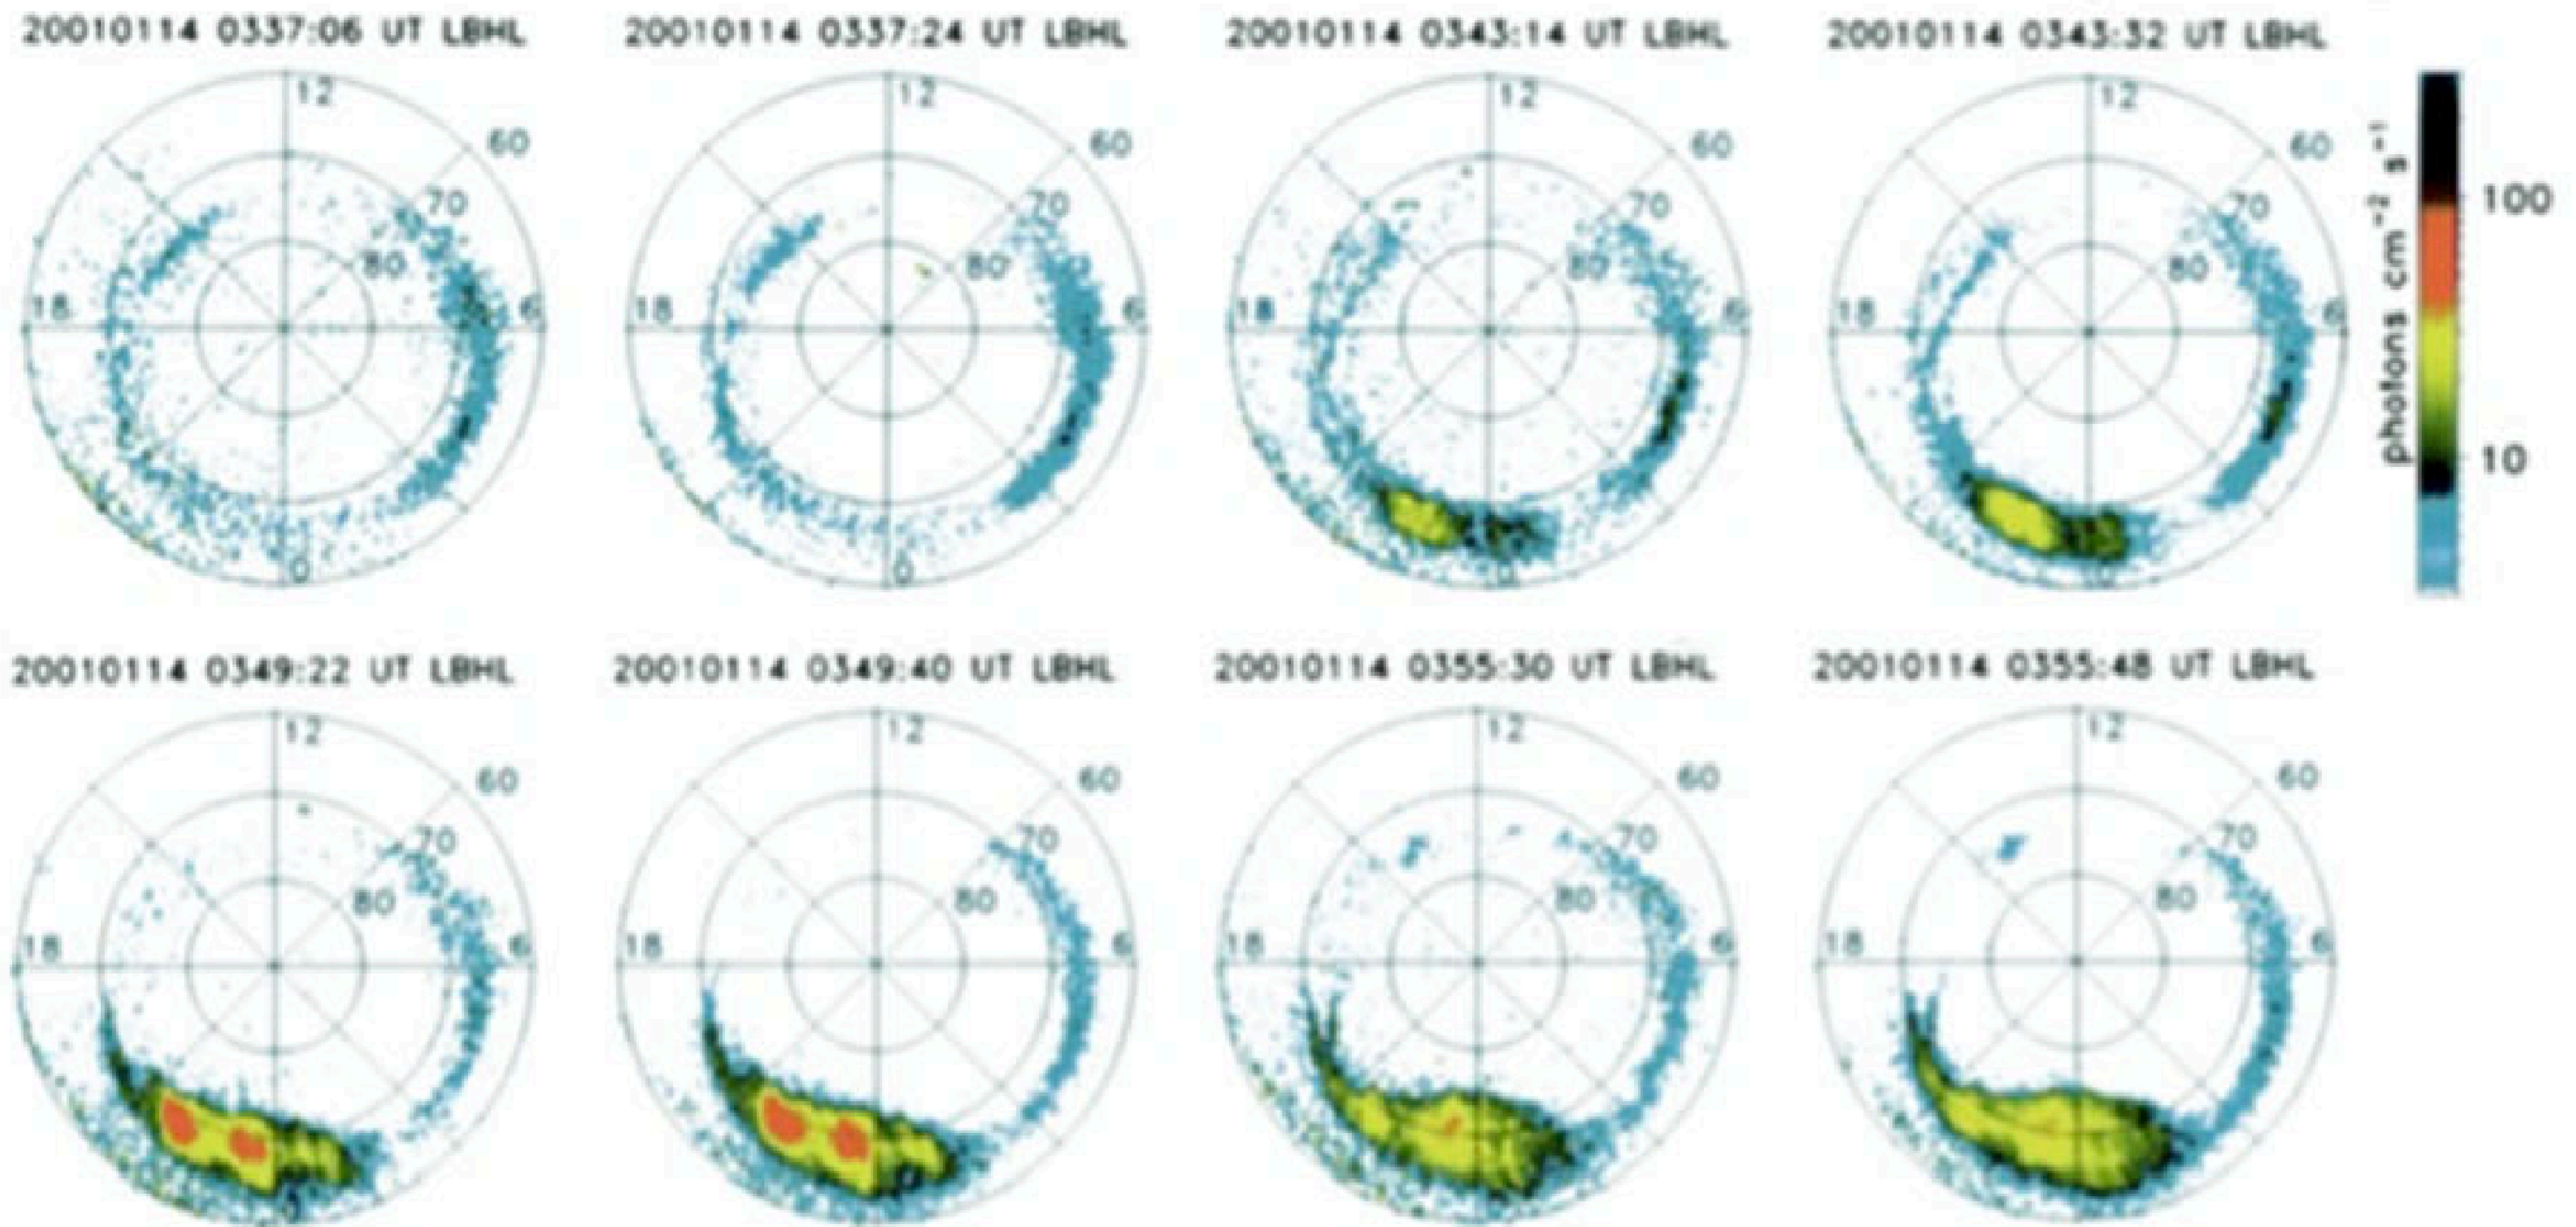

- Magnetic reconnection in the nightside magnetotail follows dayside reconnection (~2.5 hr quasiperiodicity)
- Current is diverted from the plasma sheet to the auroral electrojet in ionosphere
- Strengthened ionospheric currents measured with ground magnetometer networks

AKR and Substorms

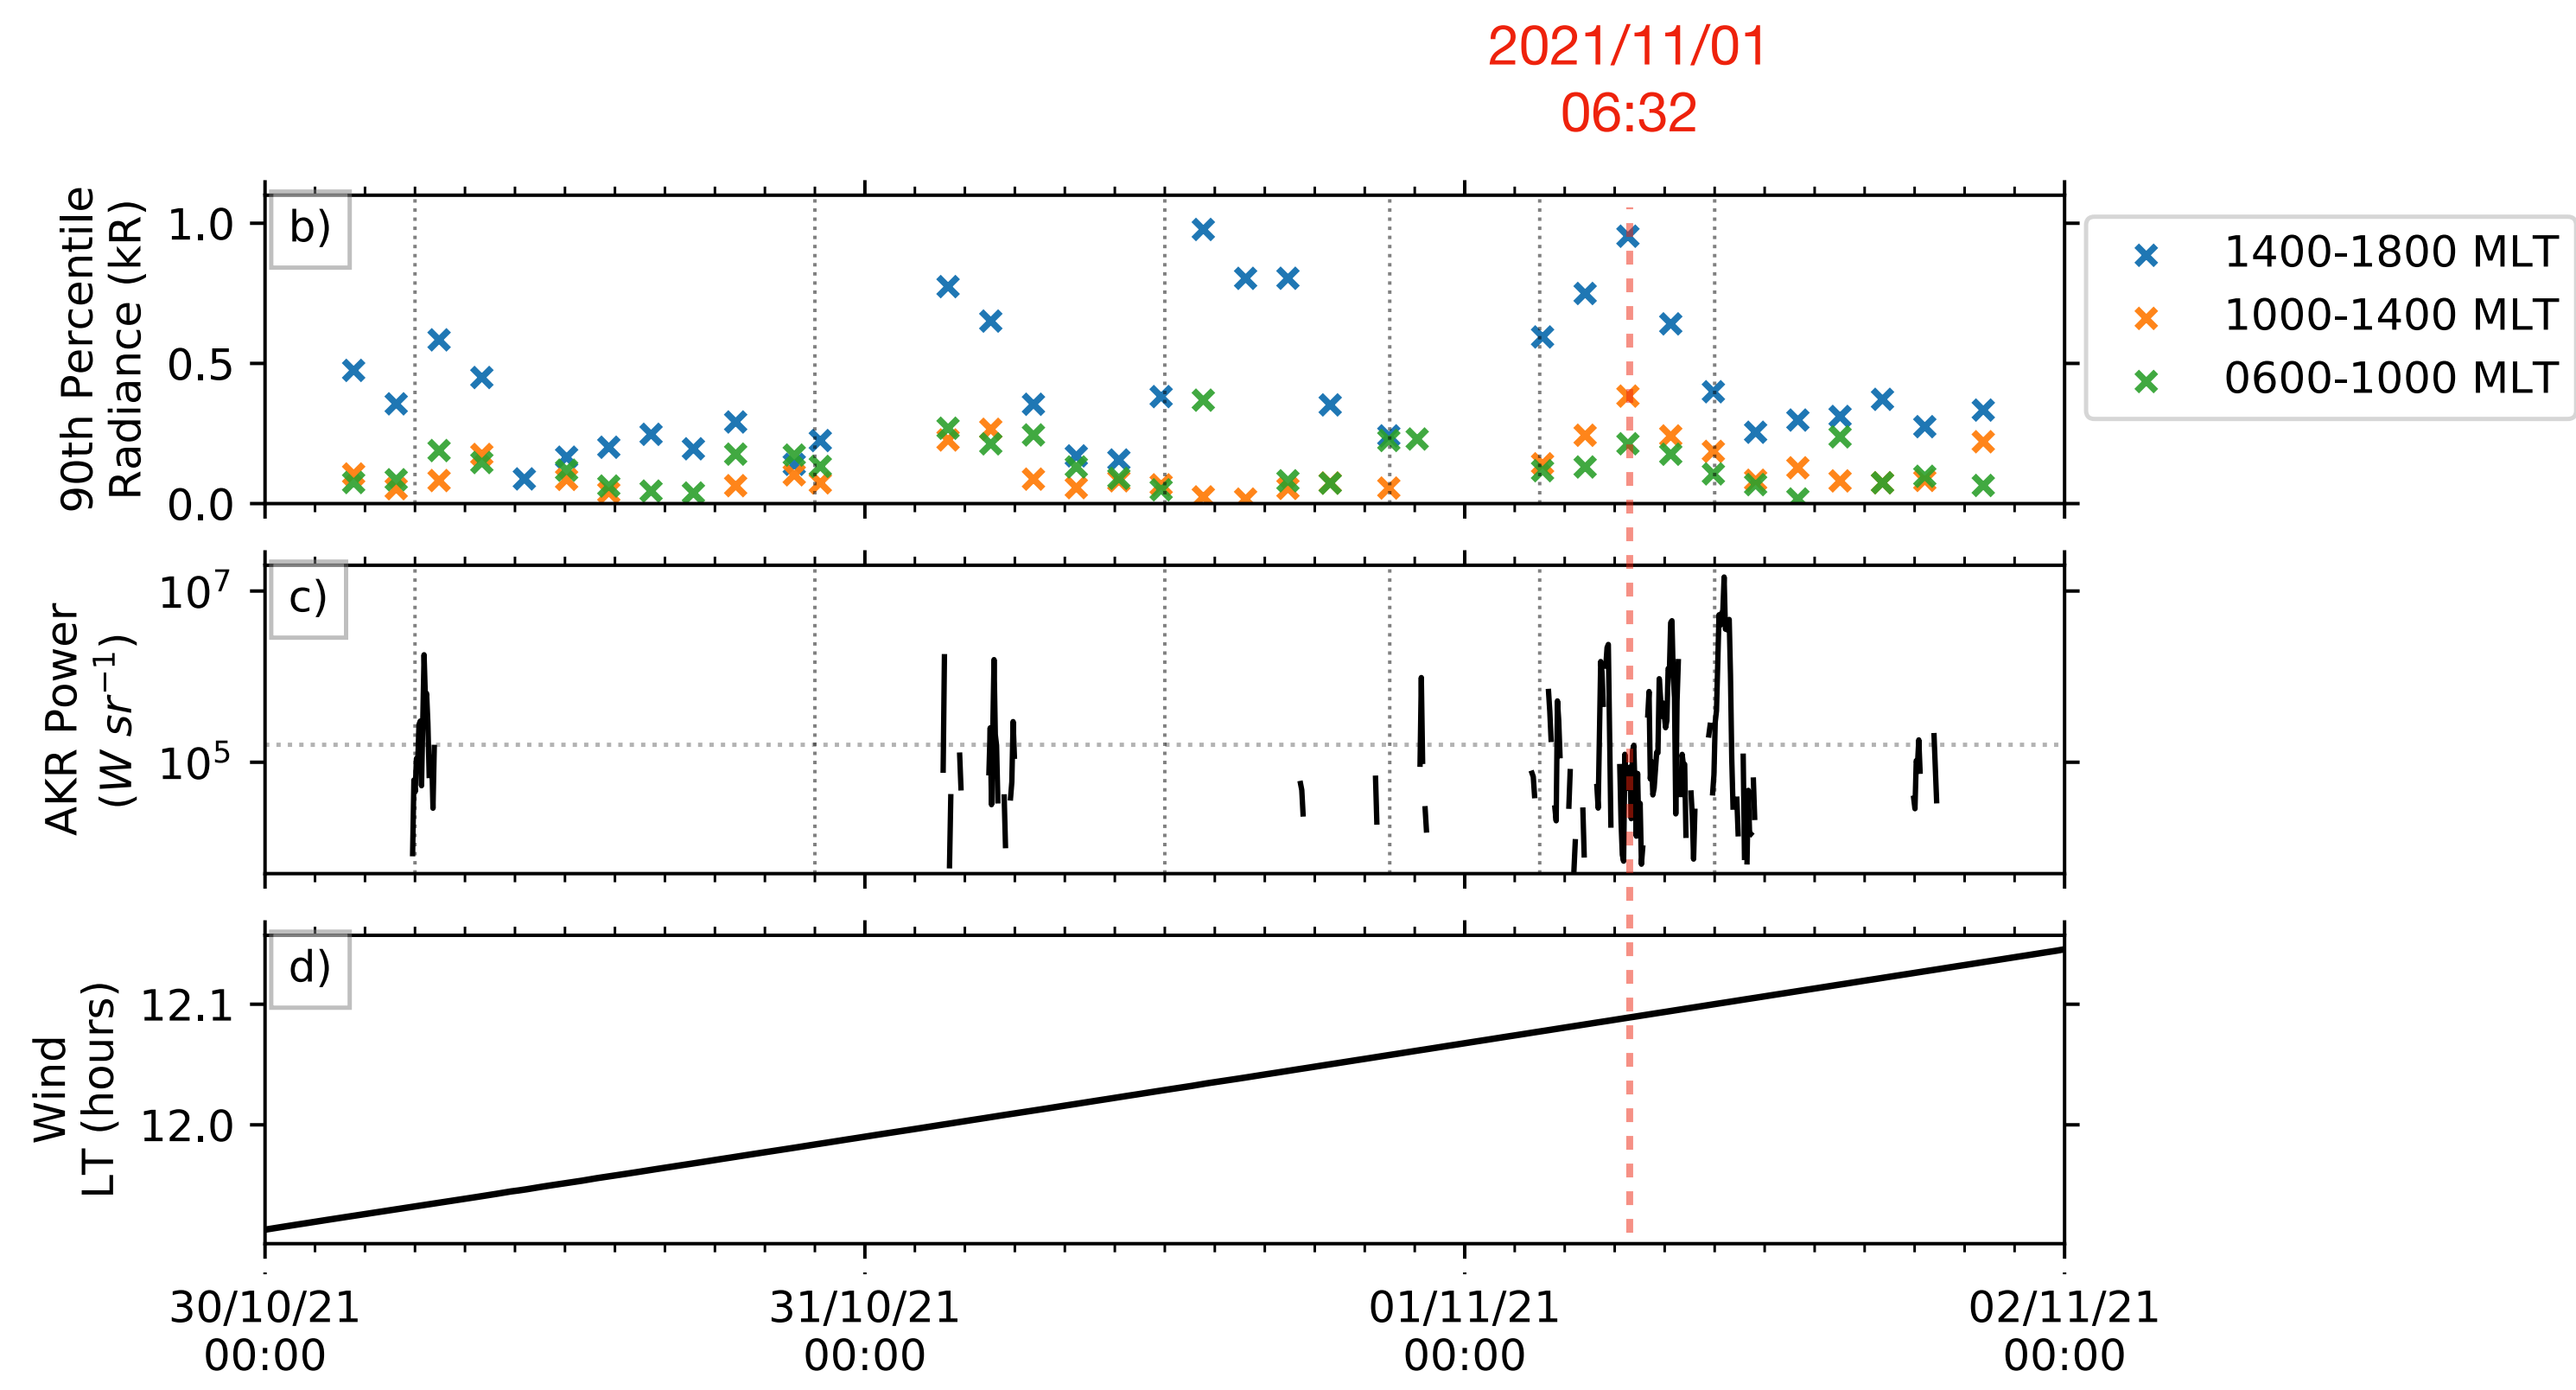

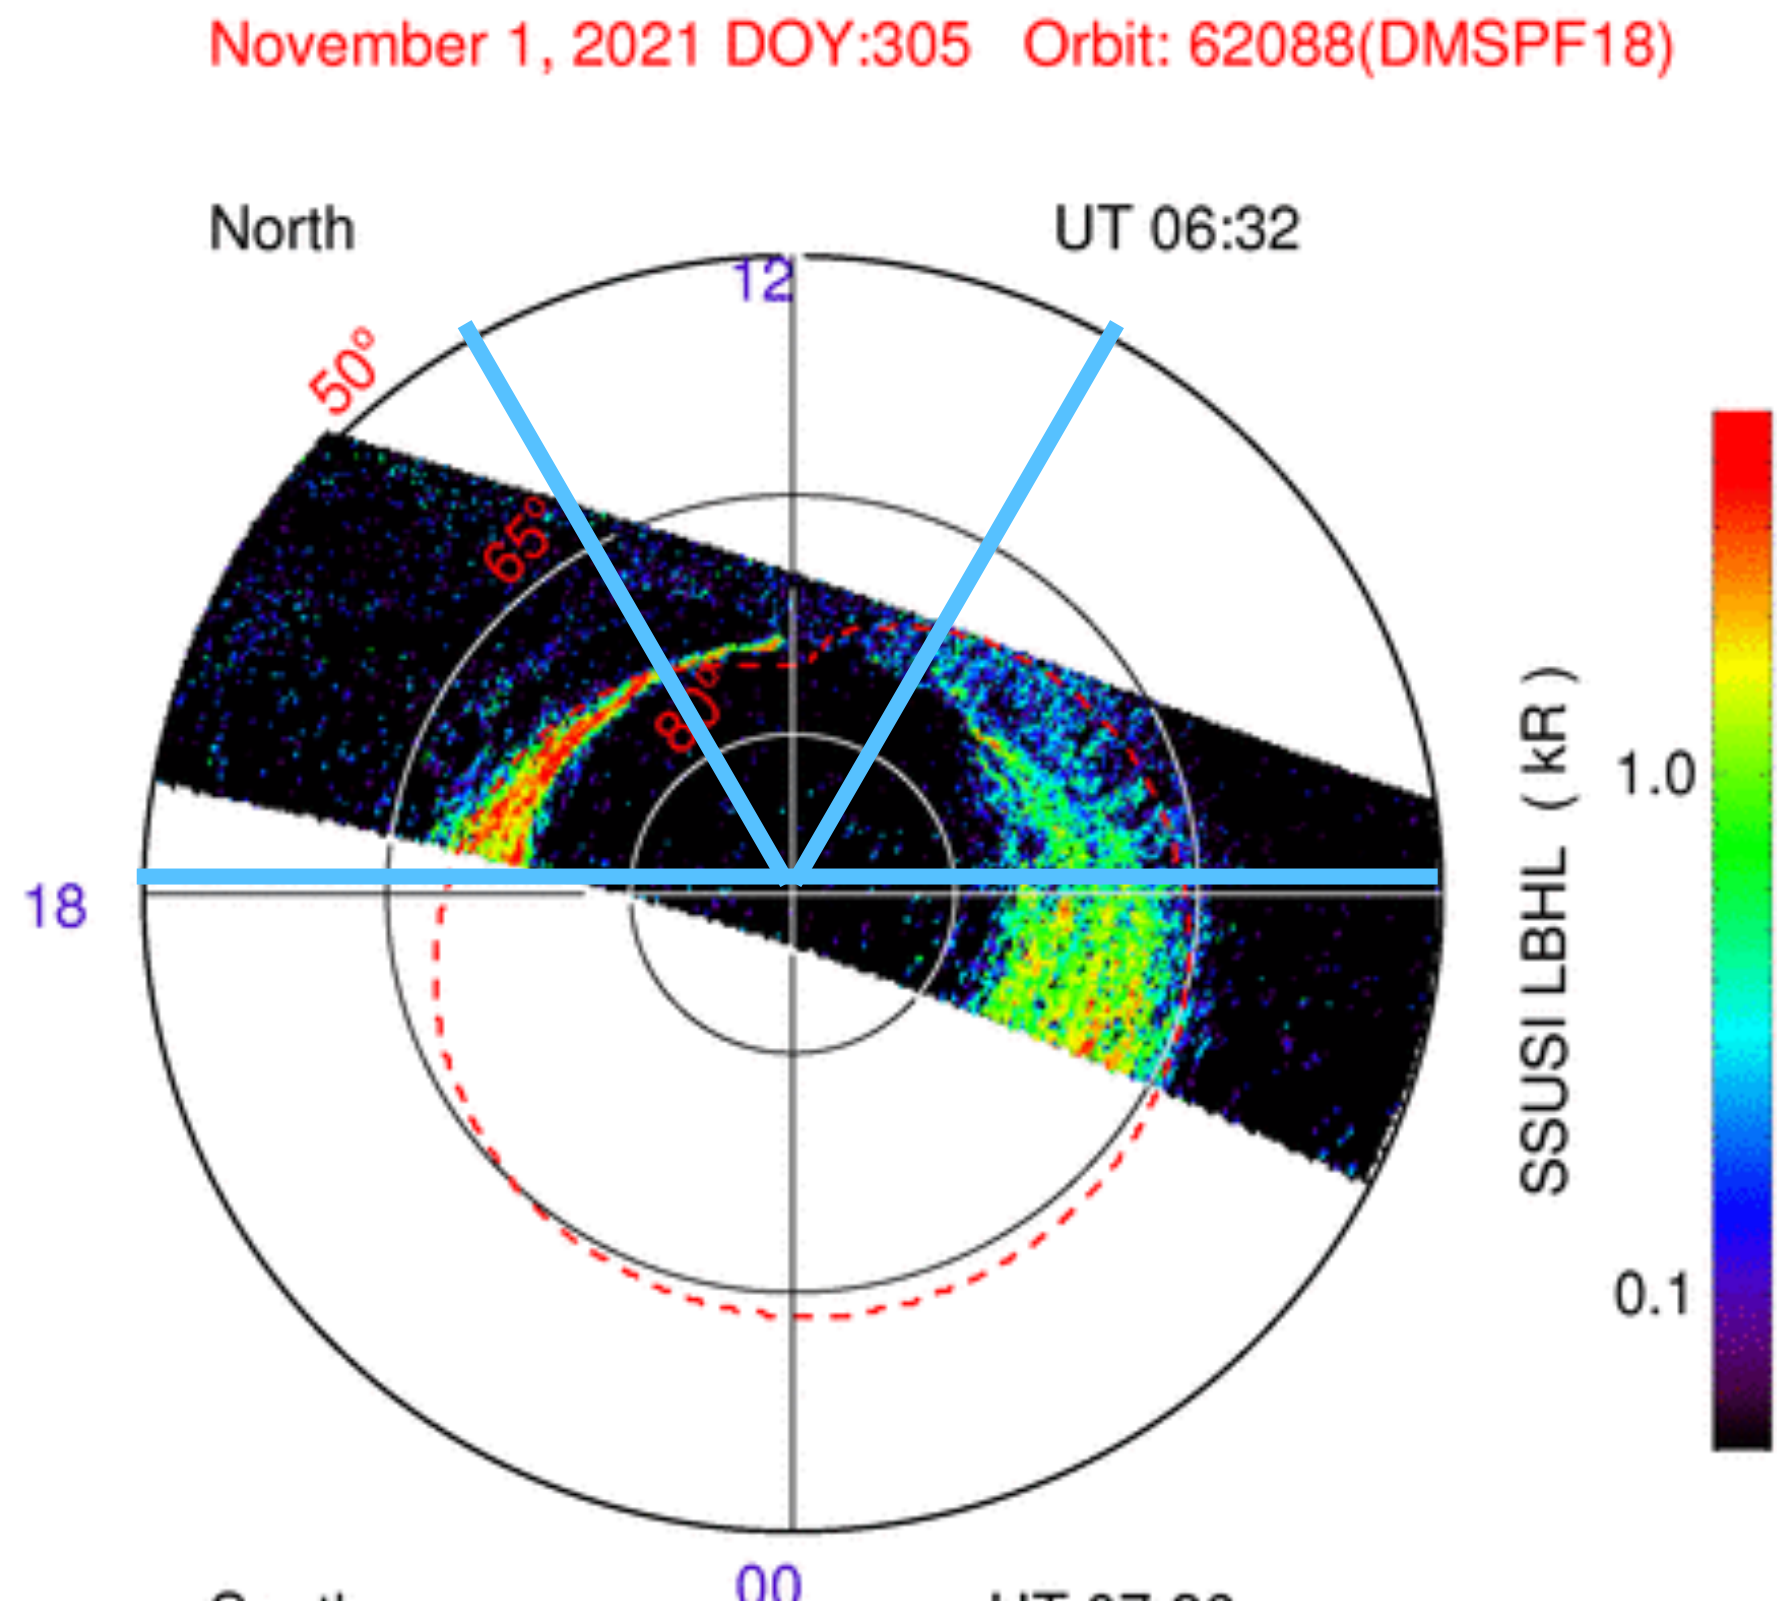

- AKR known to exhibit low frequency activity around substorm activity
- Showed statistically for first time with 10 years of Wind/Waves observations (Waters+ 2022)
- Strengthened ionospheric currents measured with ground magnetometer networks

Substorms - auroral morphology

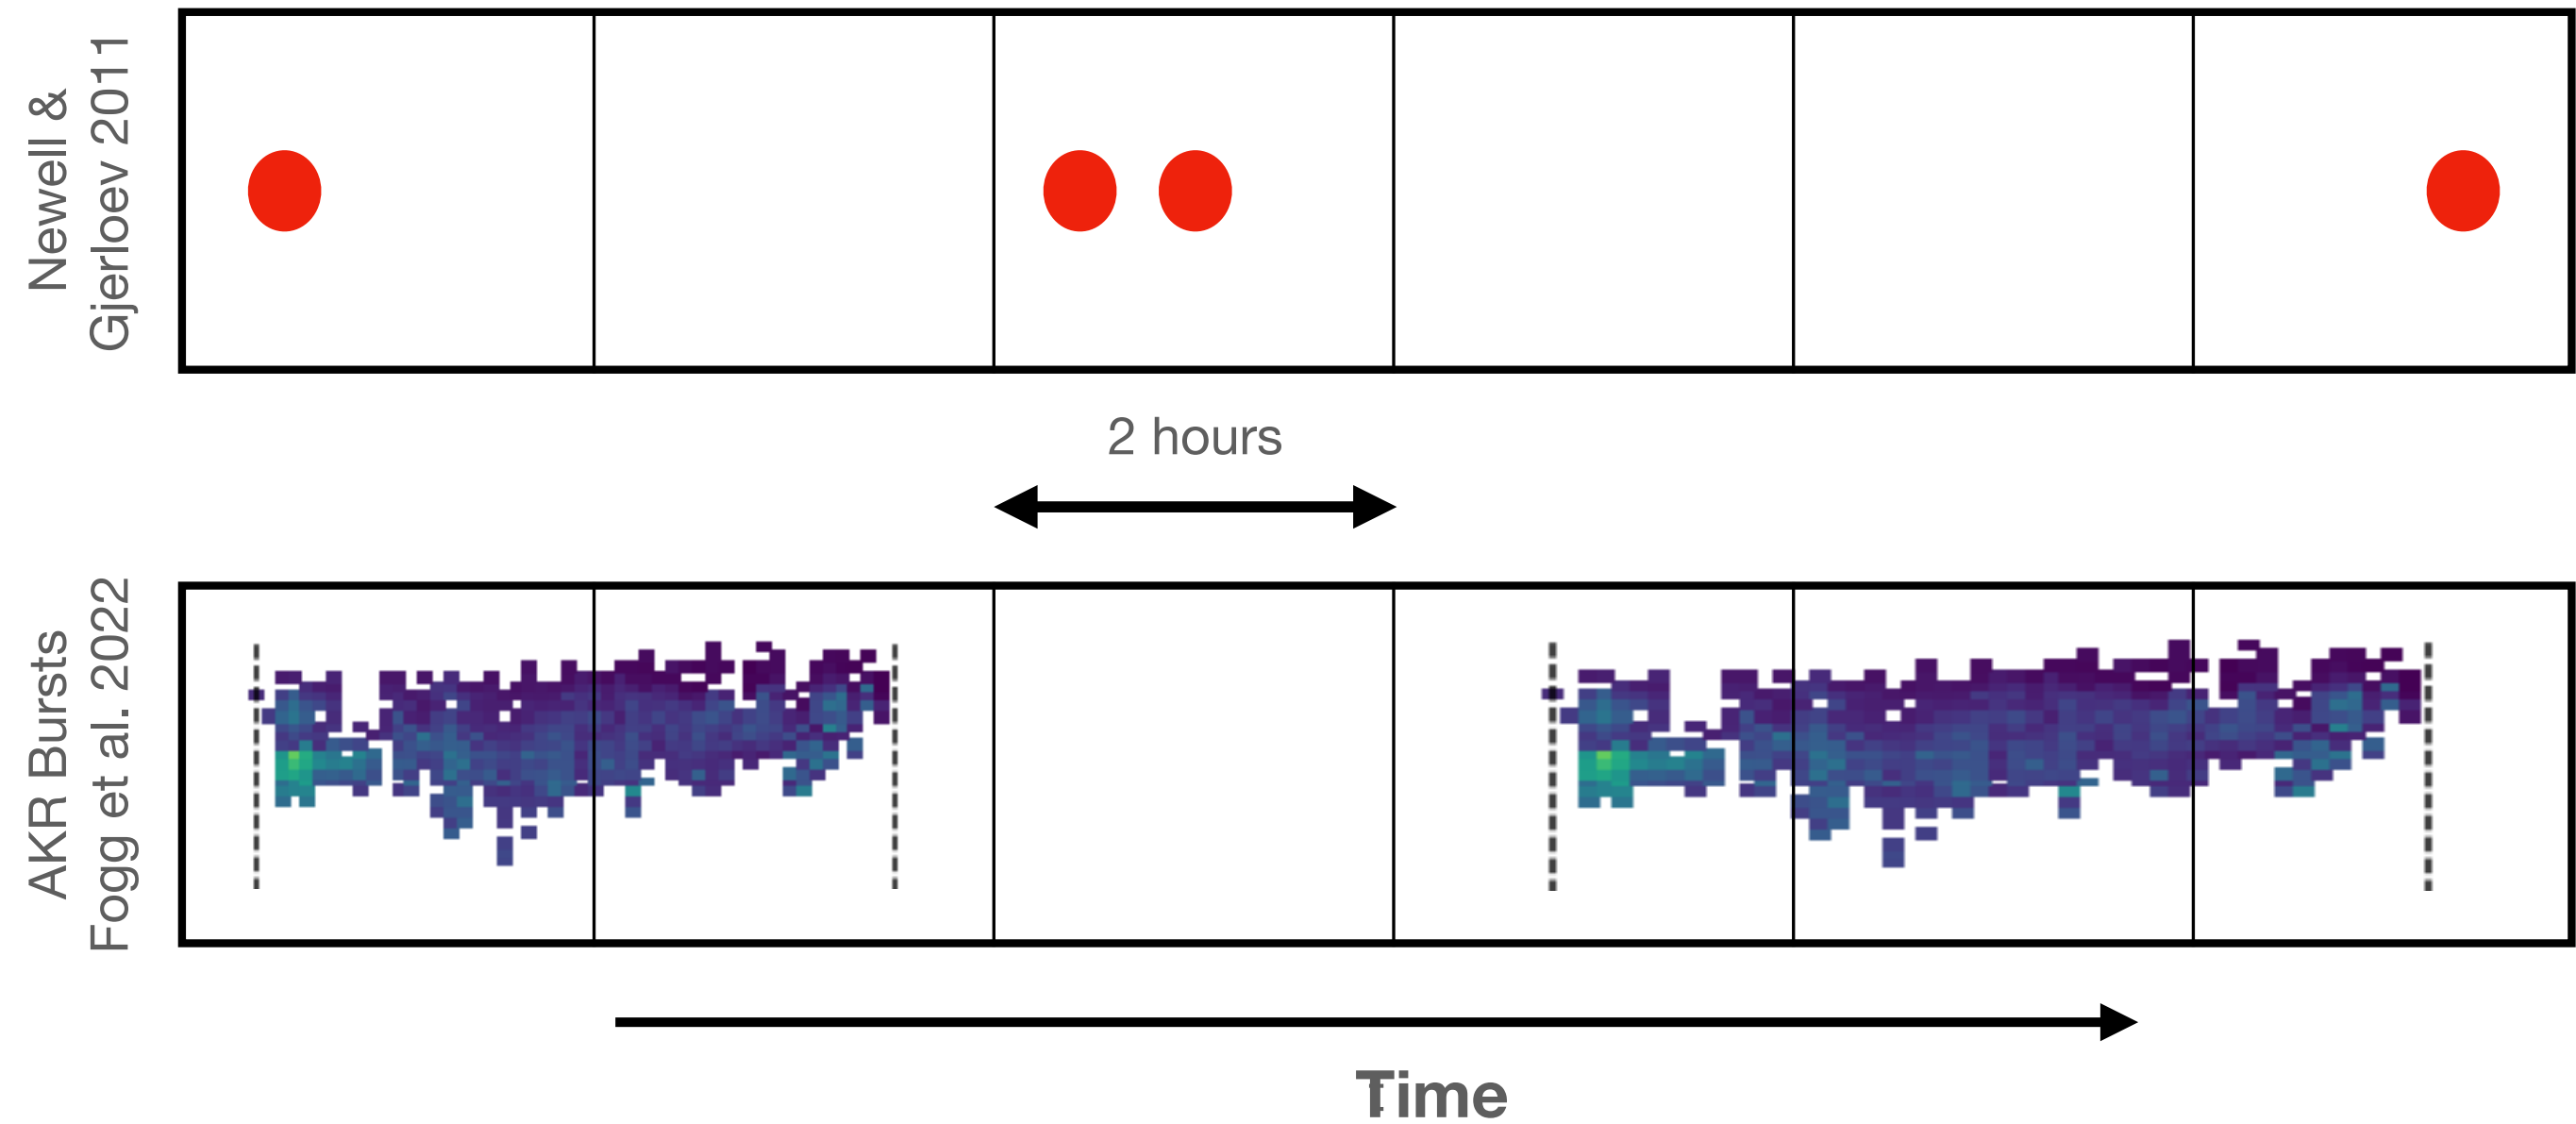

- Polar UVI Observations during substorm onset (Akasofu 2017)

AKR and Substorms

Waters+ 2023

Binary classification of substorms with remote AKR observations

- Using substorm event lists with appropriate coverage:
 - SuperMAG SML index; Newell & Gjerloev 2011
 - Mid-latitude positive bay index, derived from SuperMAG; Chu et al., 2015
 - SuperMAG derived, with greater constraints; Ohtani et al., 2020
 - IMAGE/WIC UV observations of substorm auroral features; Frey 2004 (not shown)

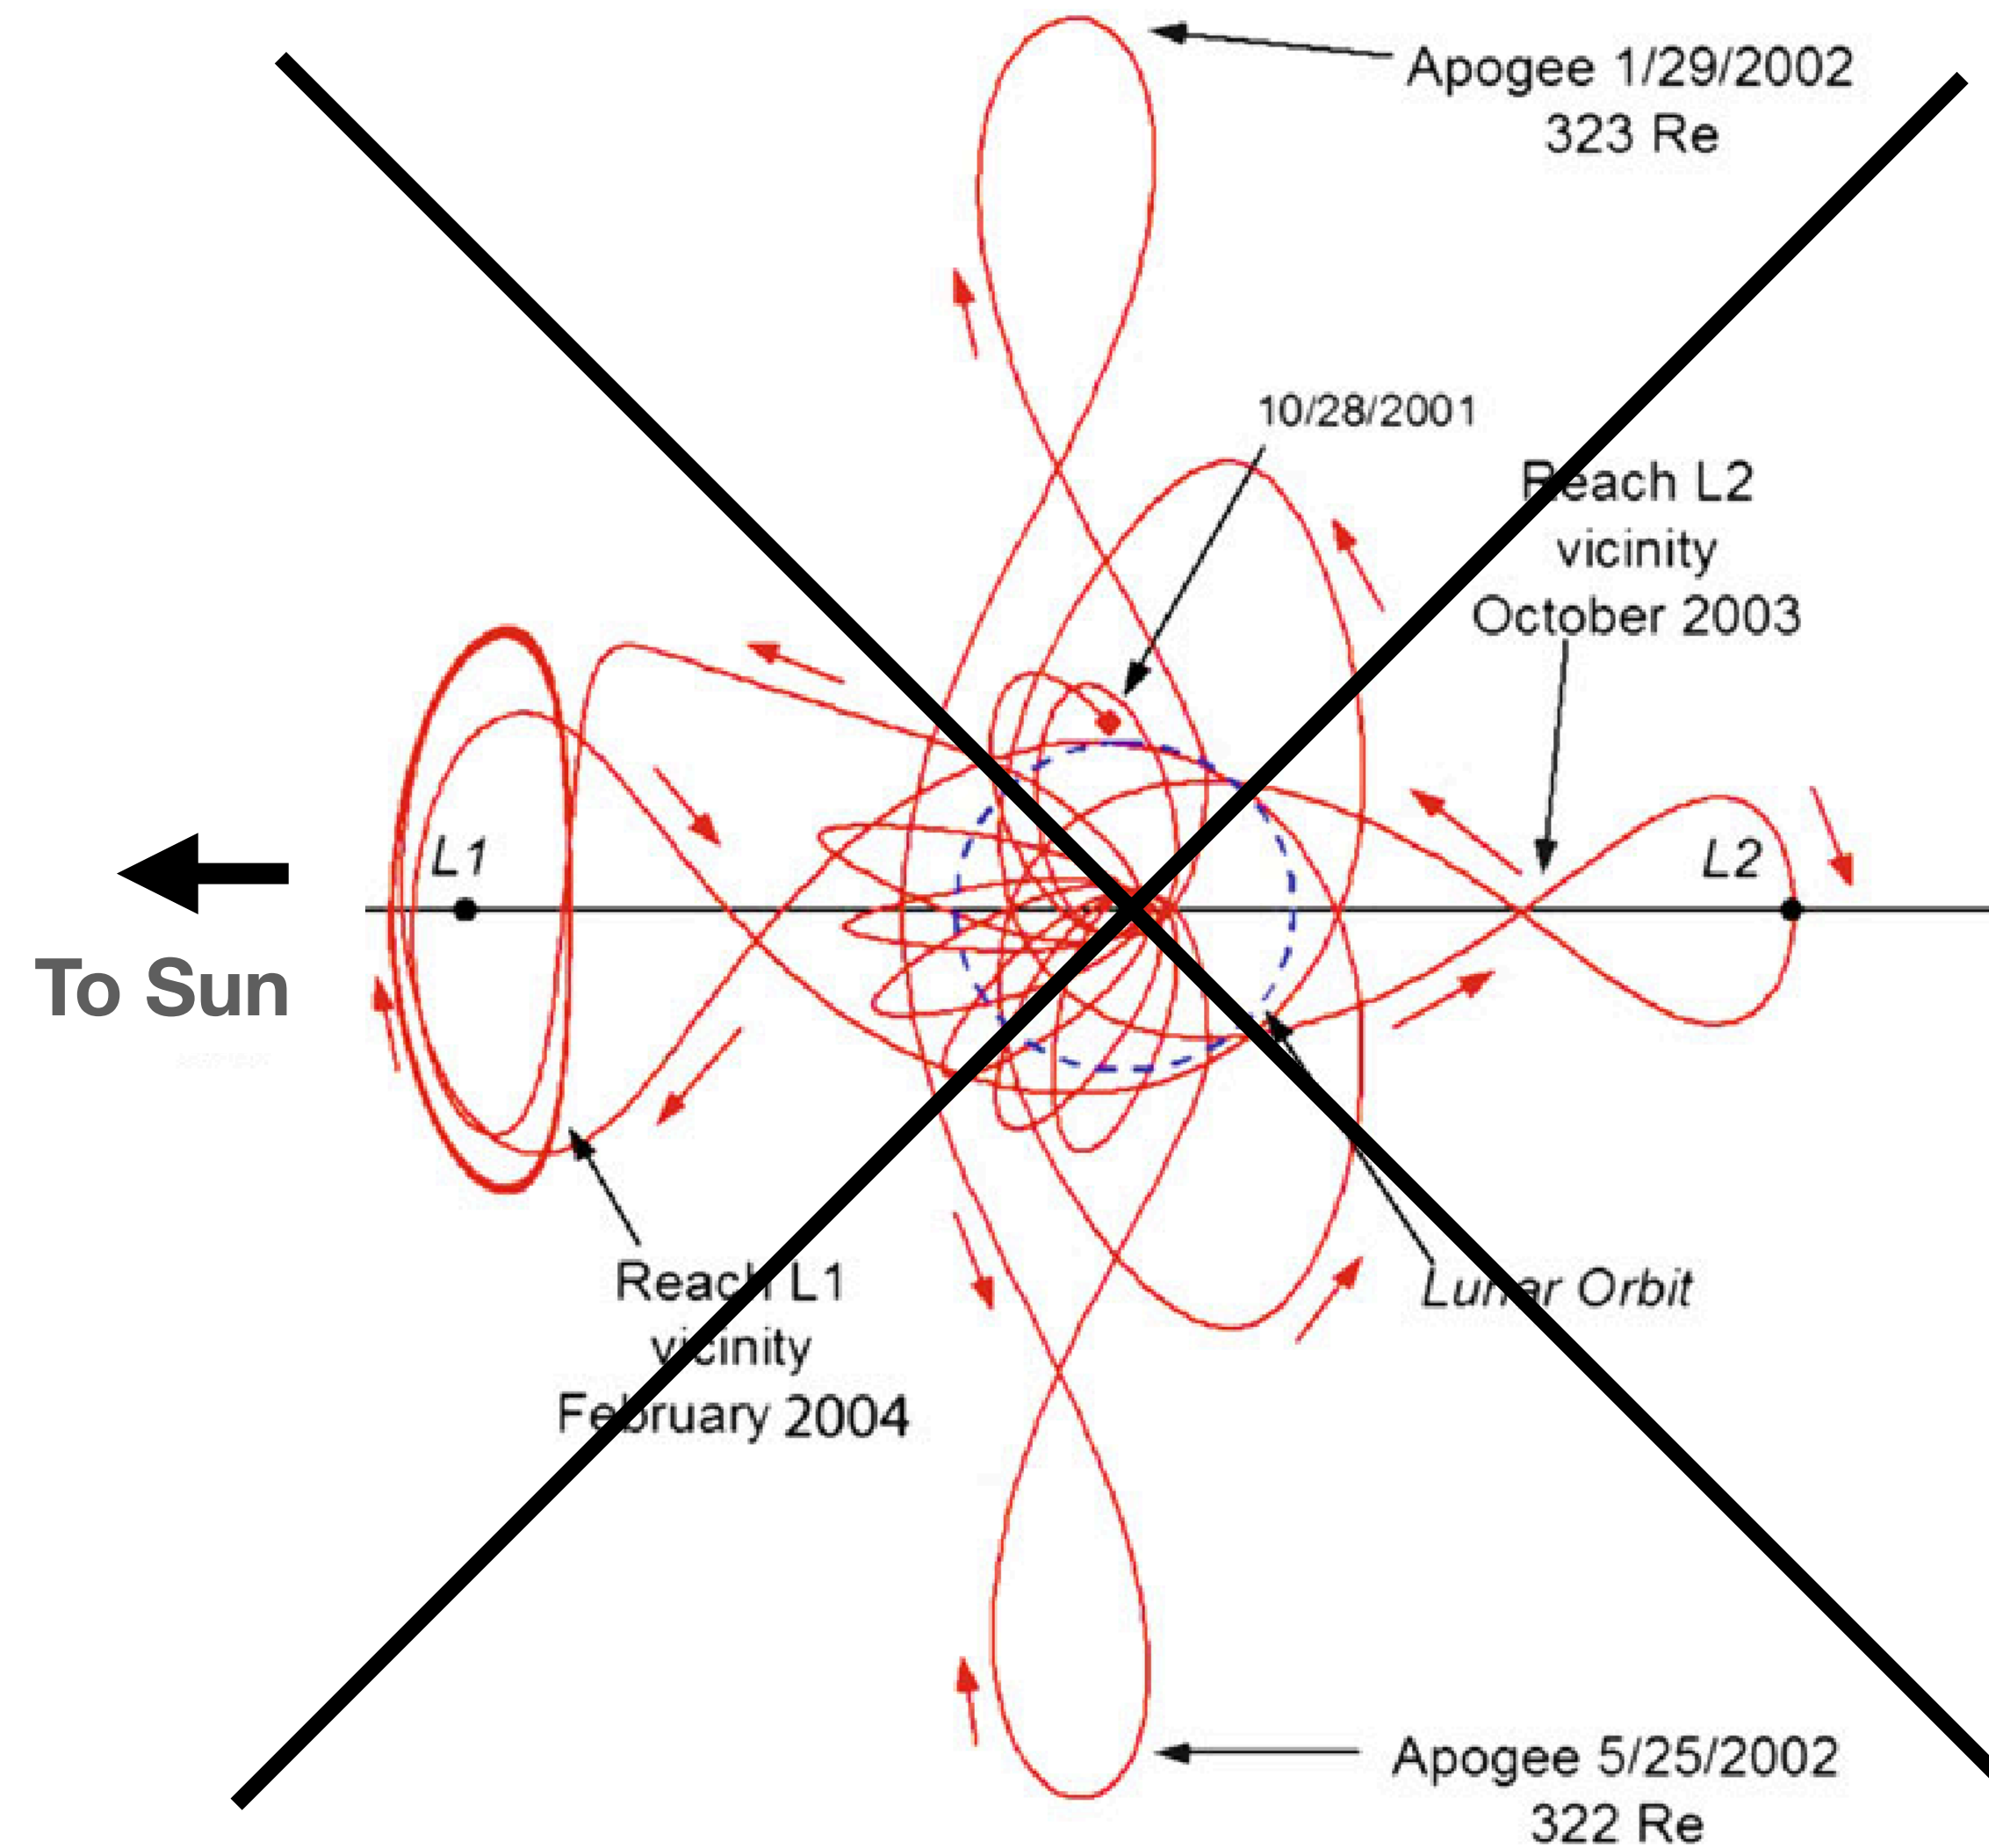

- Treat AKR in context of binary classification to assess remote observations as a “forecast proxy” for substorm onset

Substorm List
(SuperMAG)

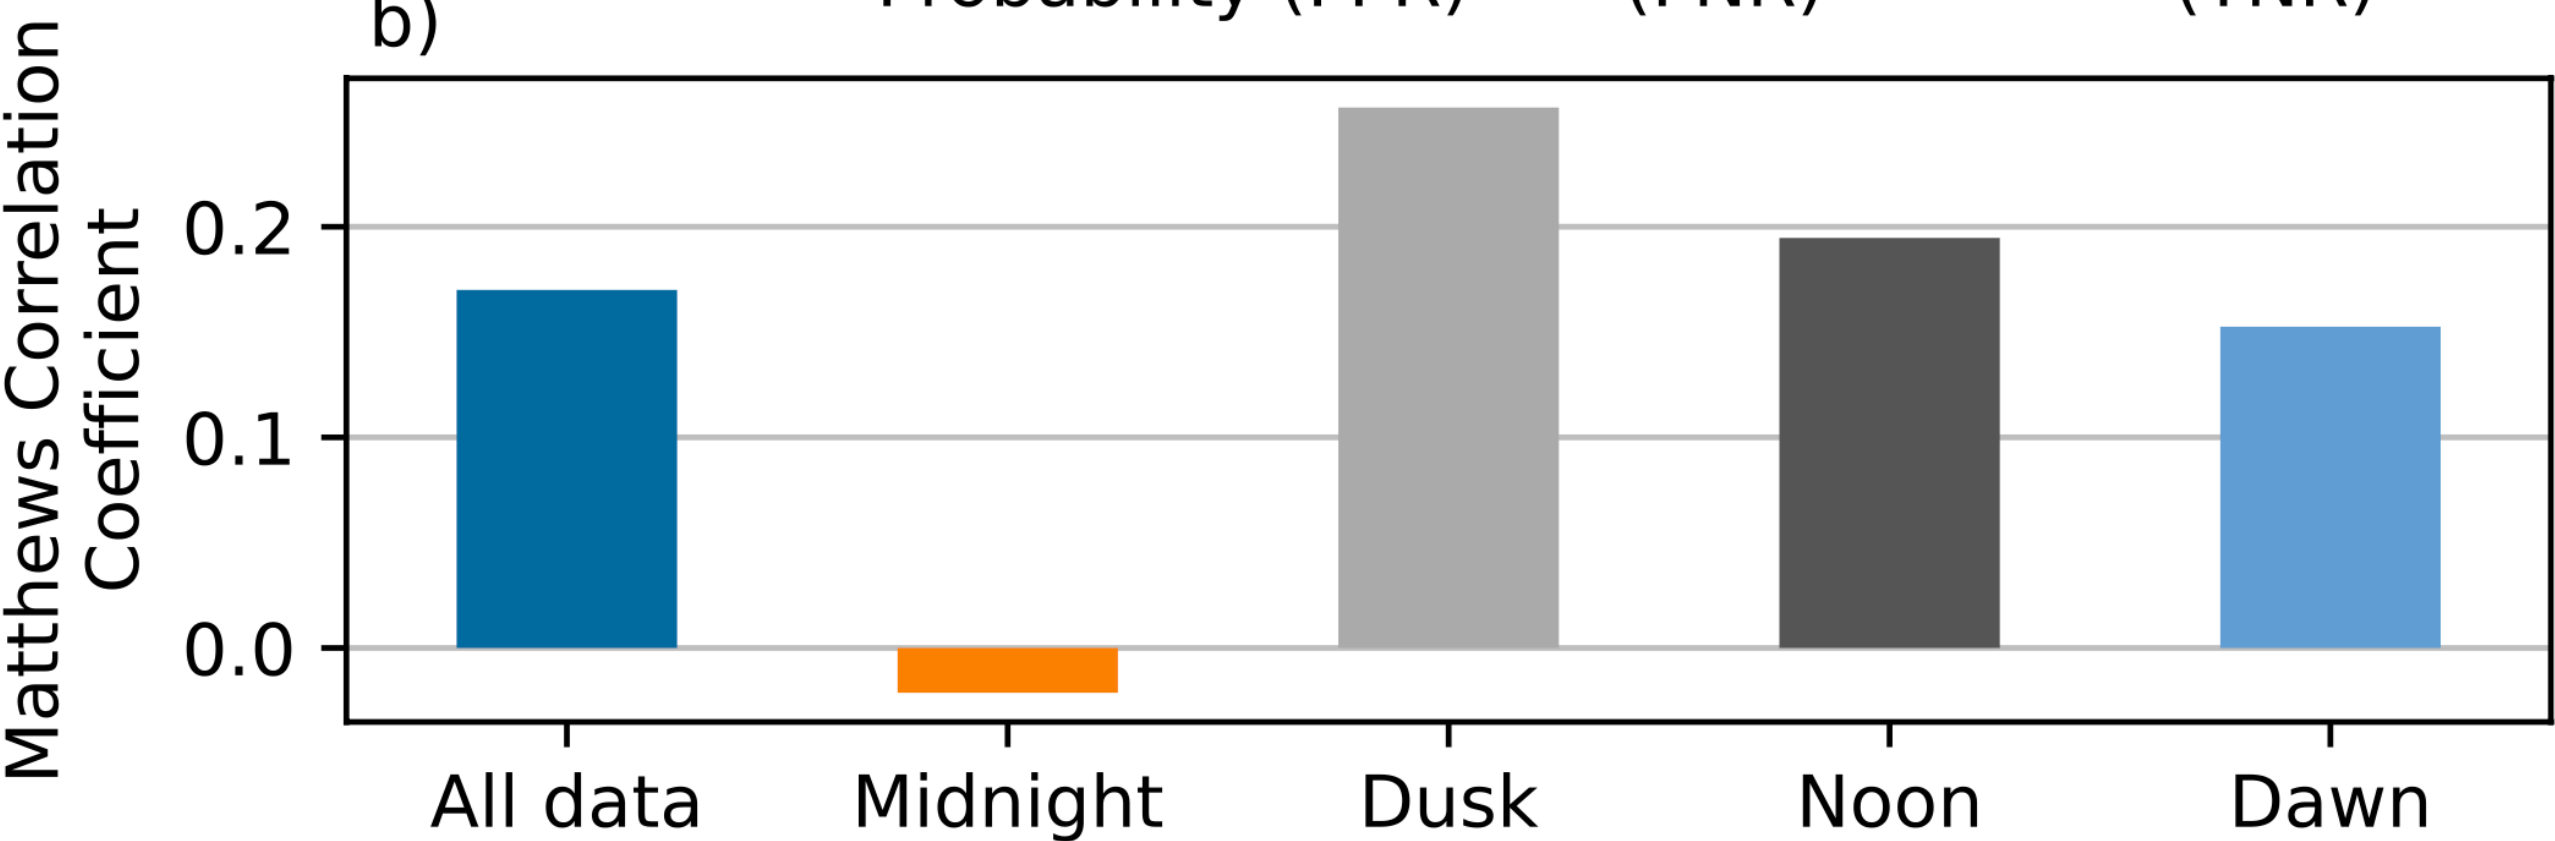

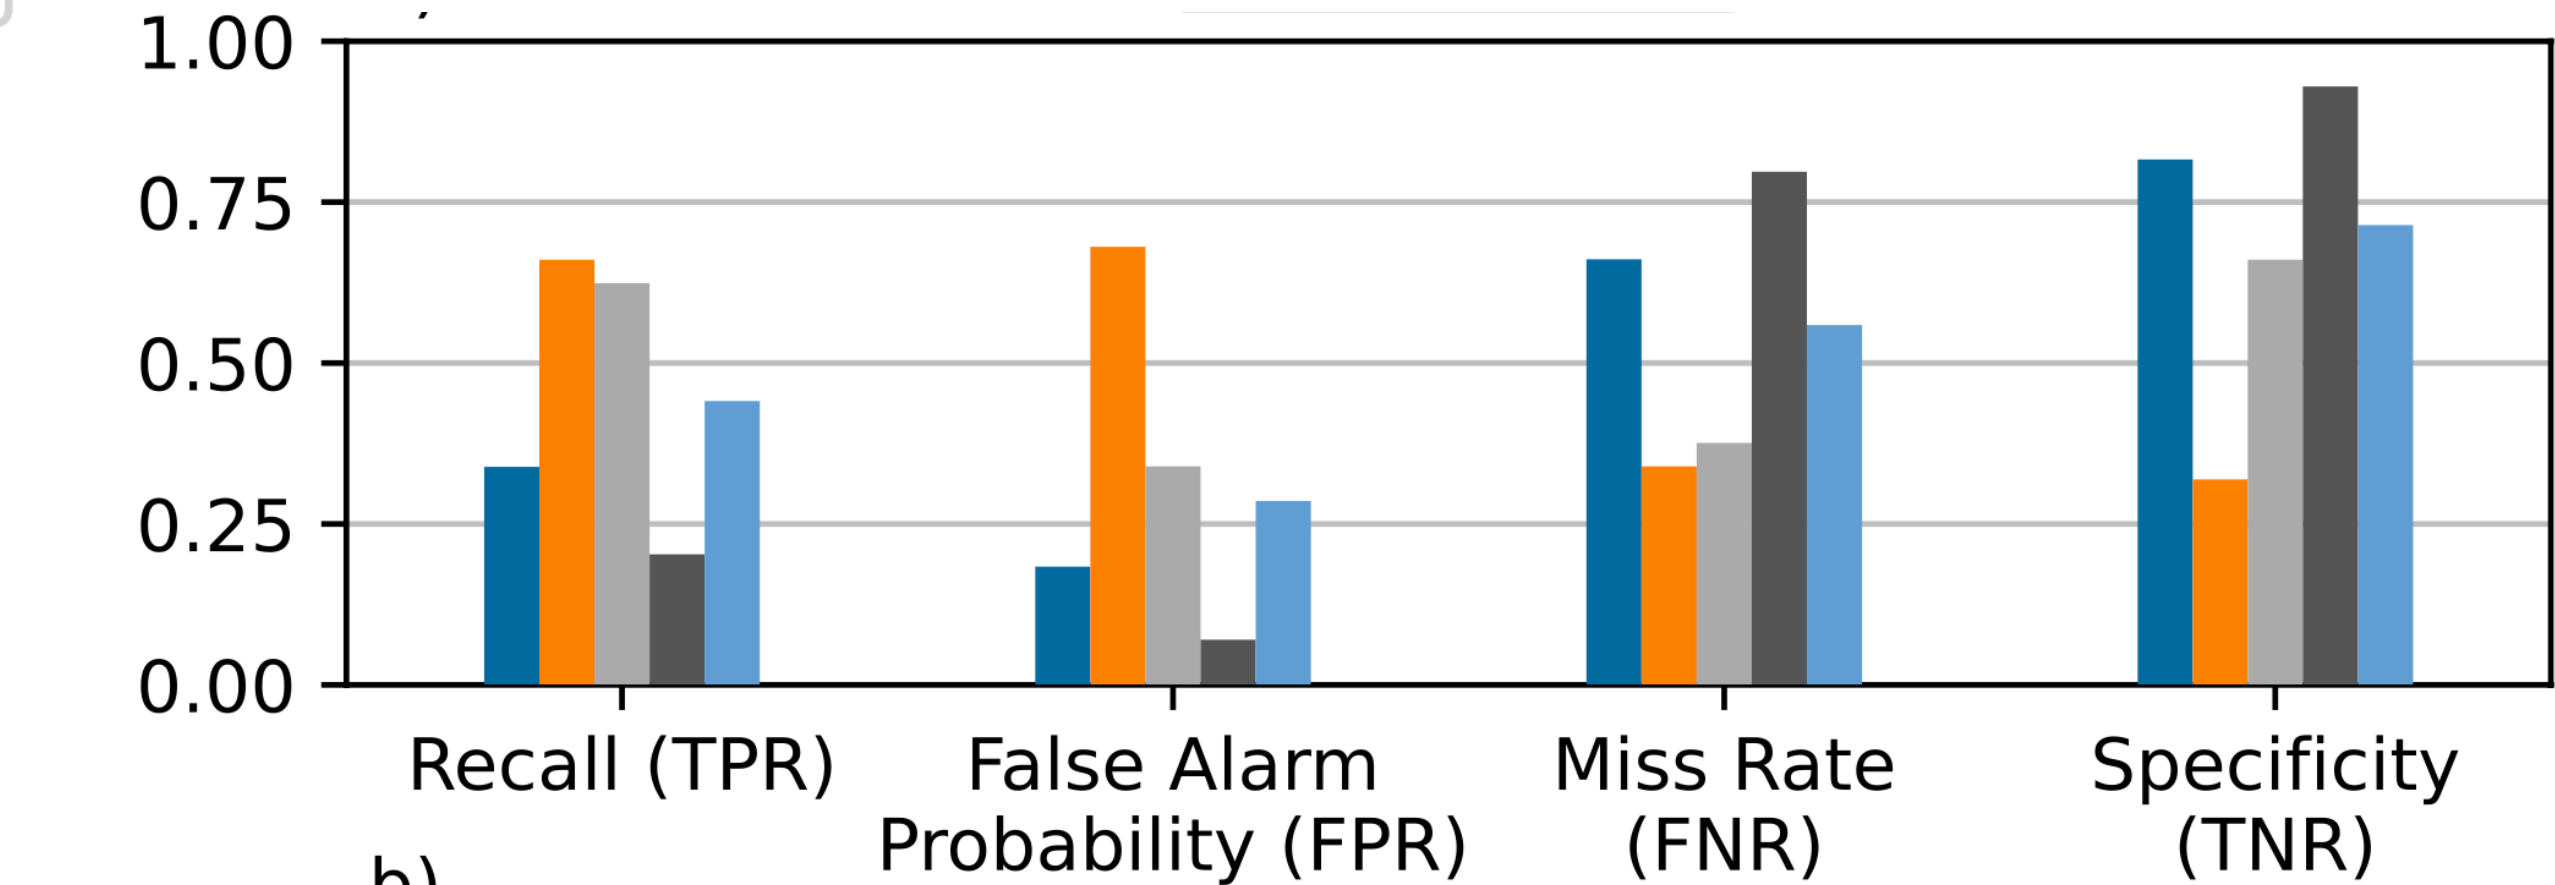

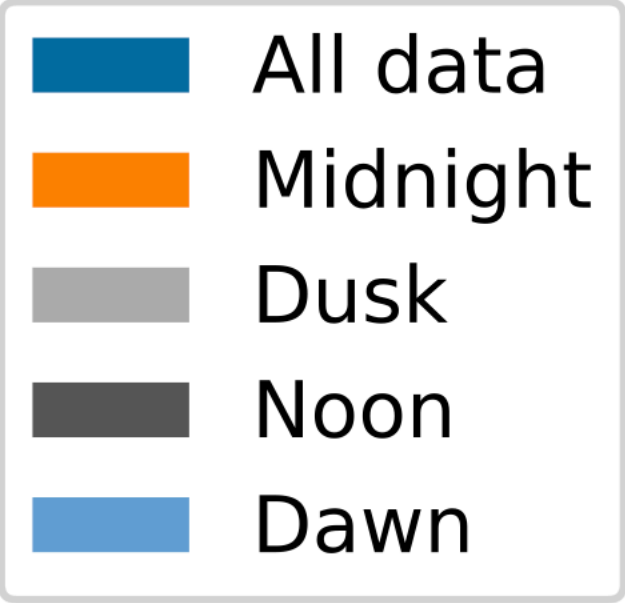

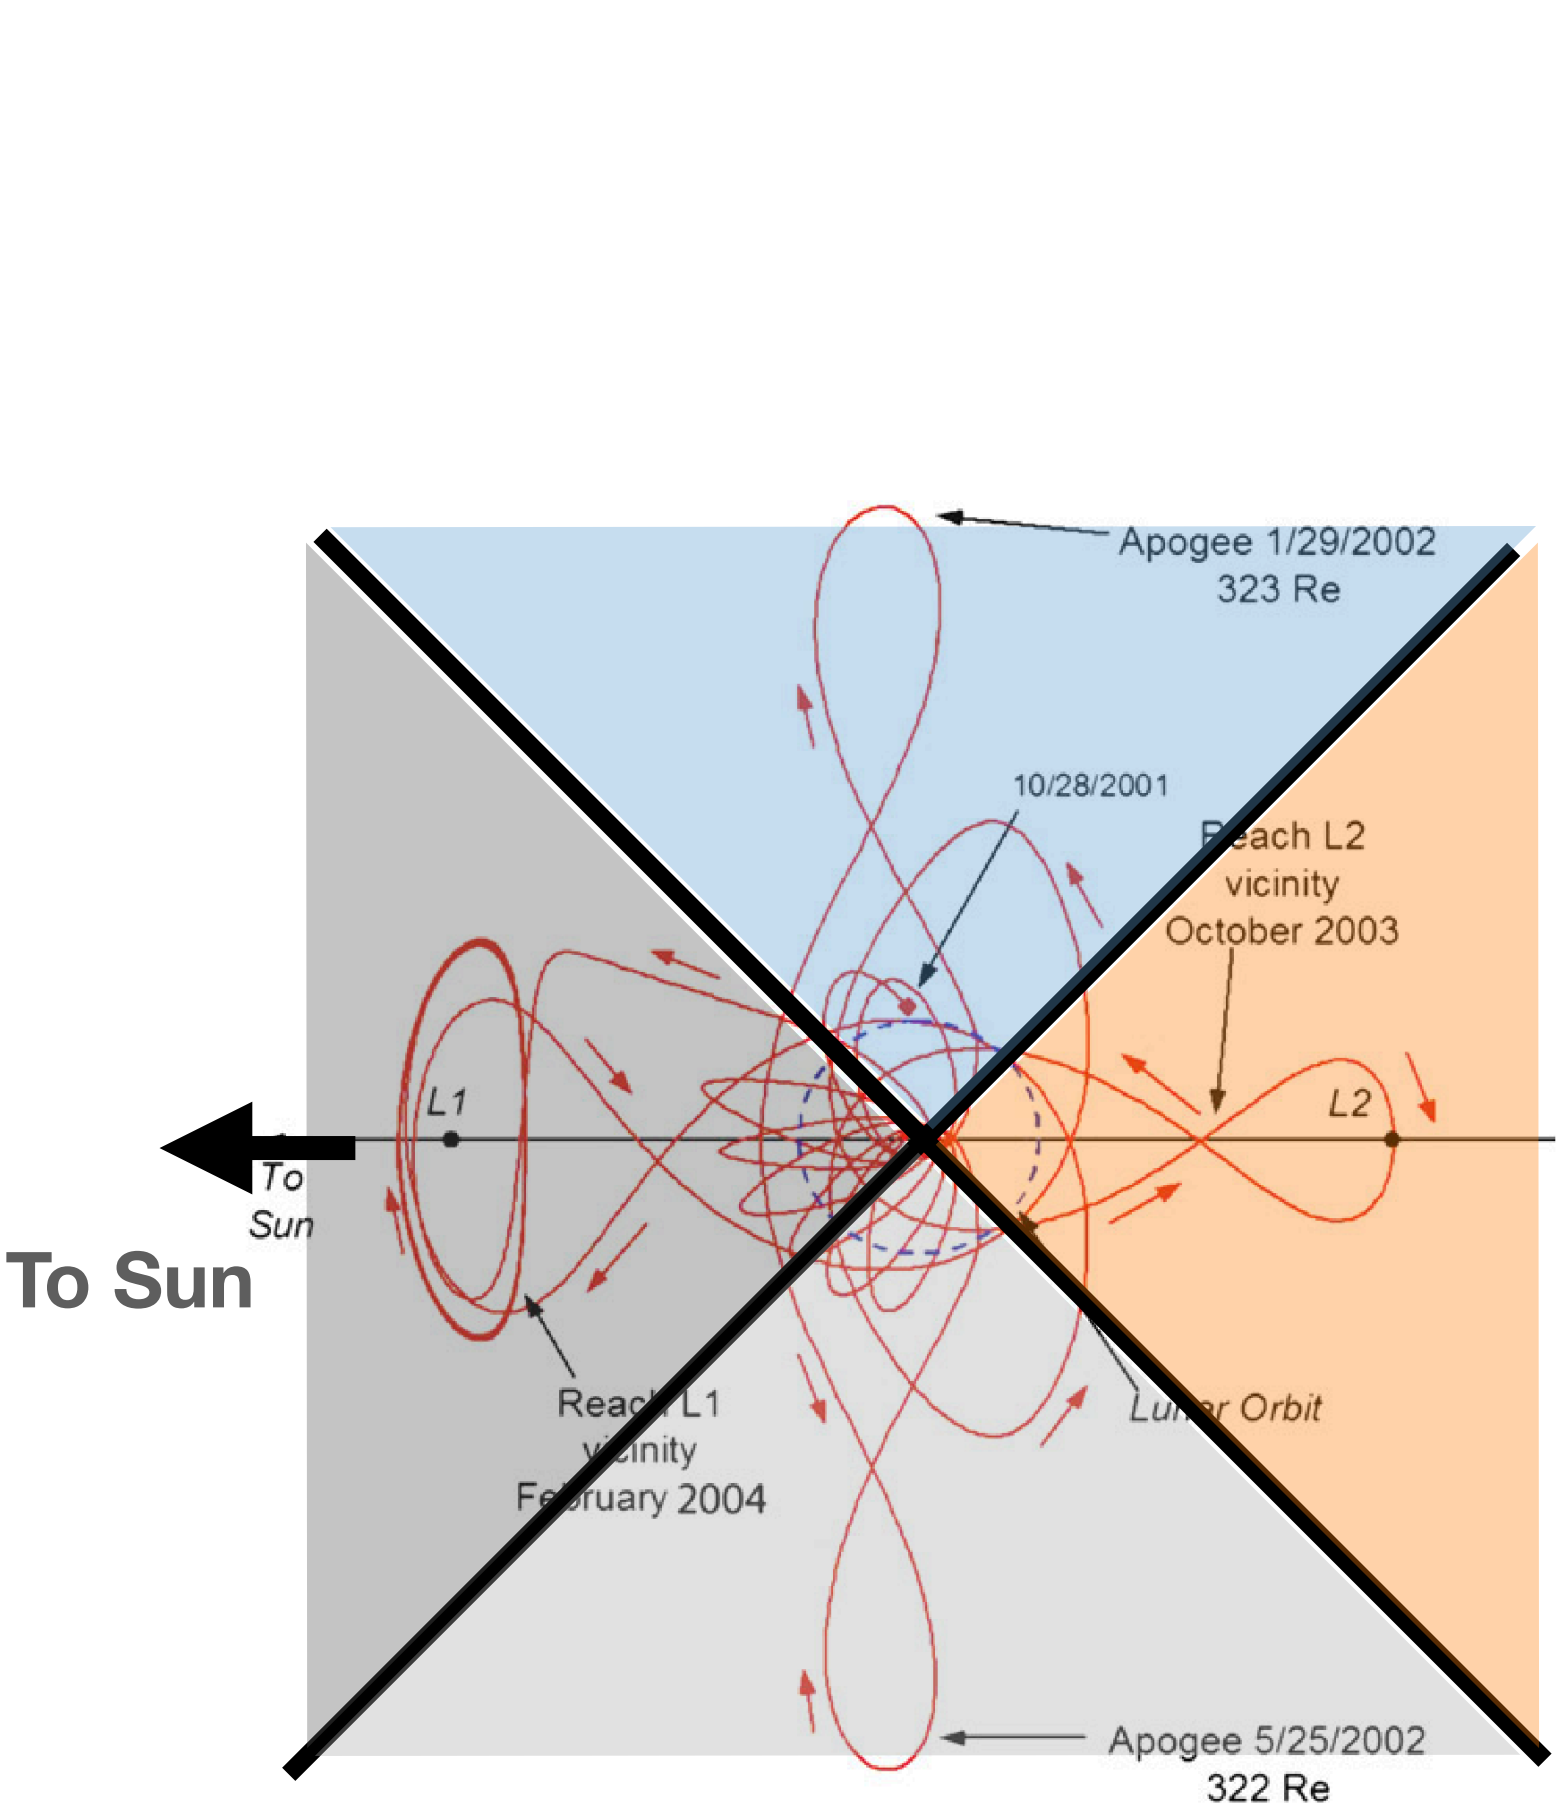

Wind AKR bursts

	Predicted positive	Predicted negative
Real positive	4599	8958
Real negative	5566	24701

Binary classification of substorms with remote AKR observations

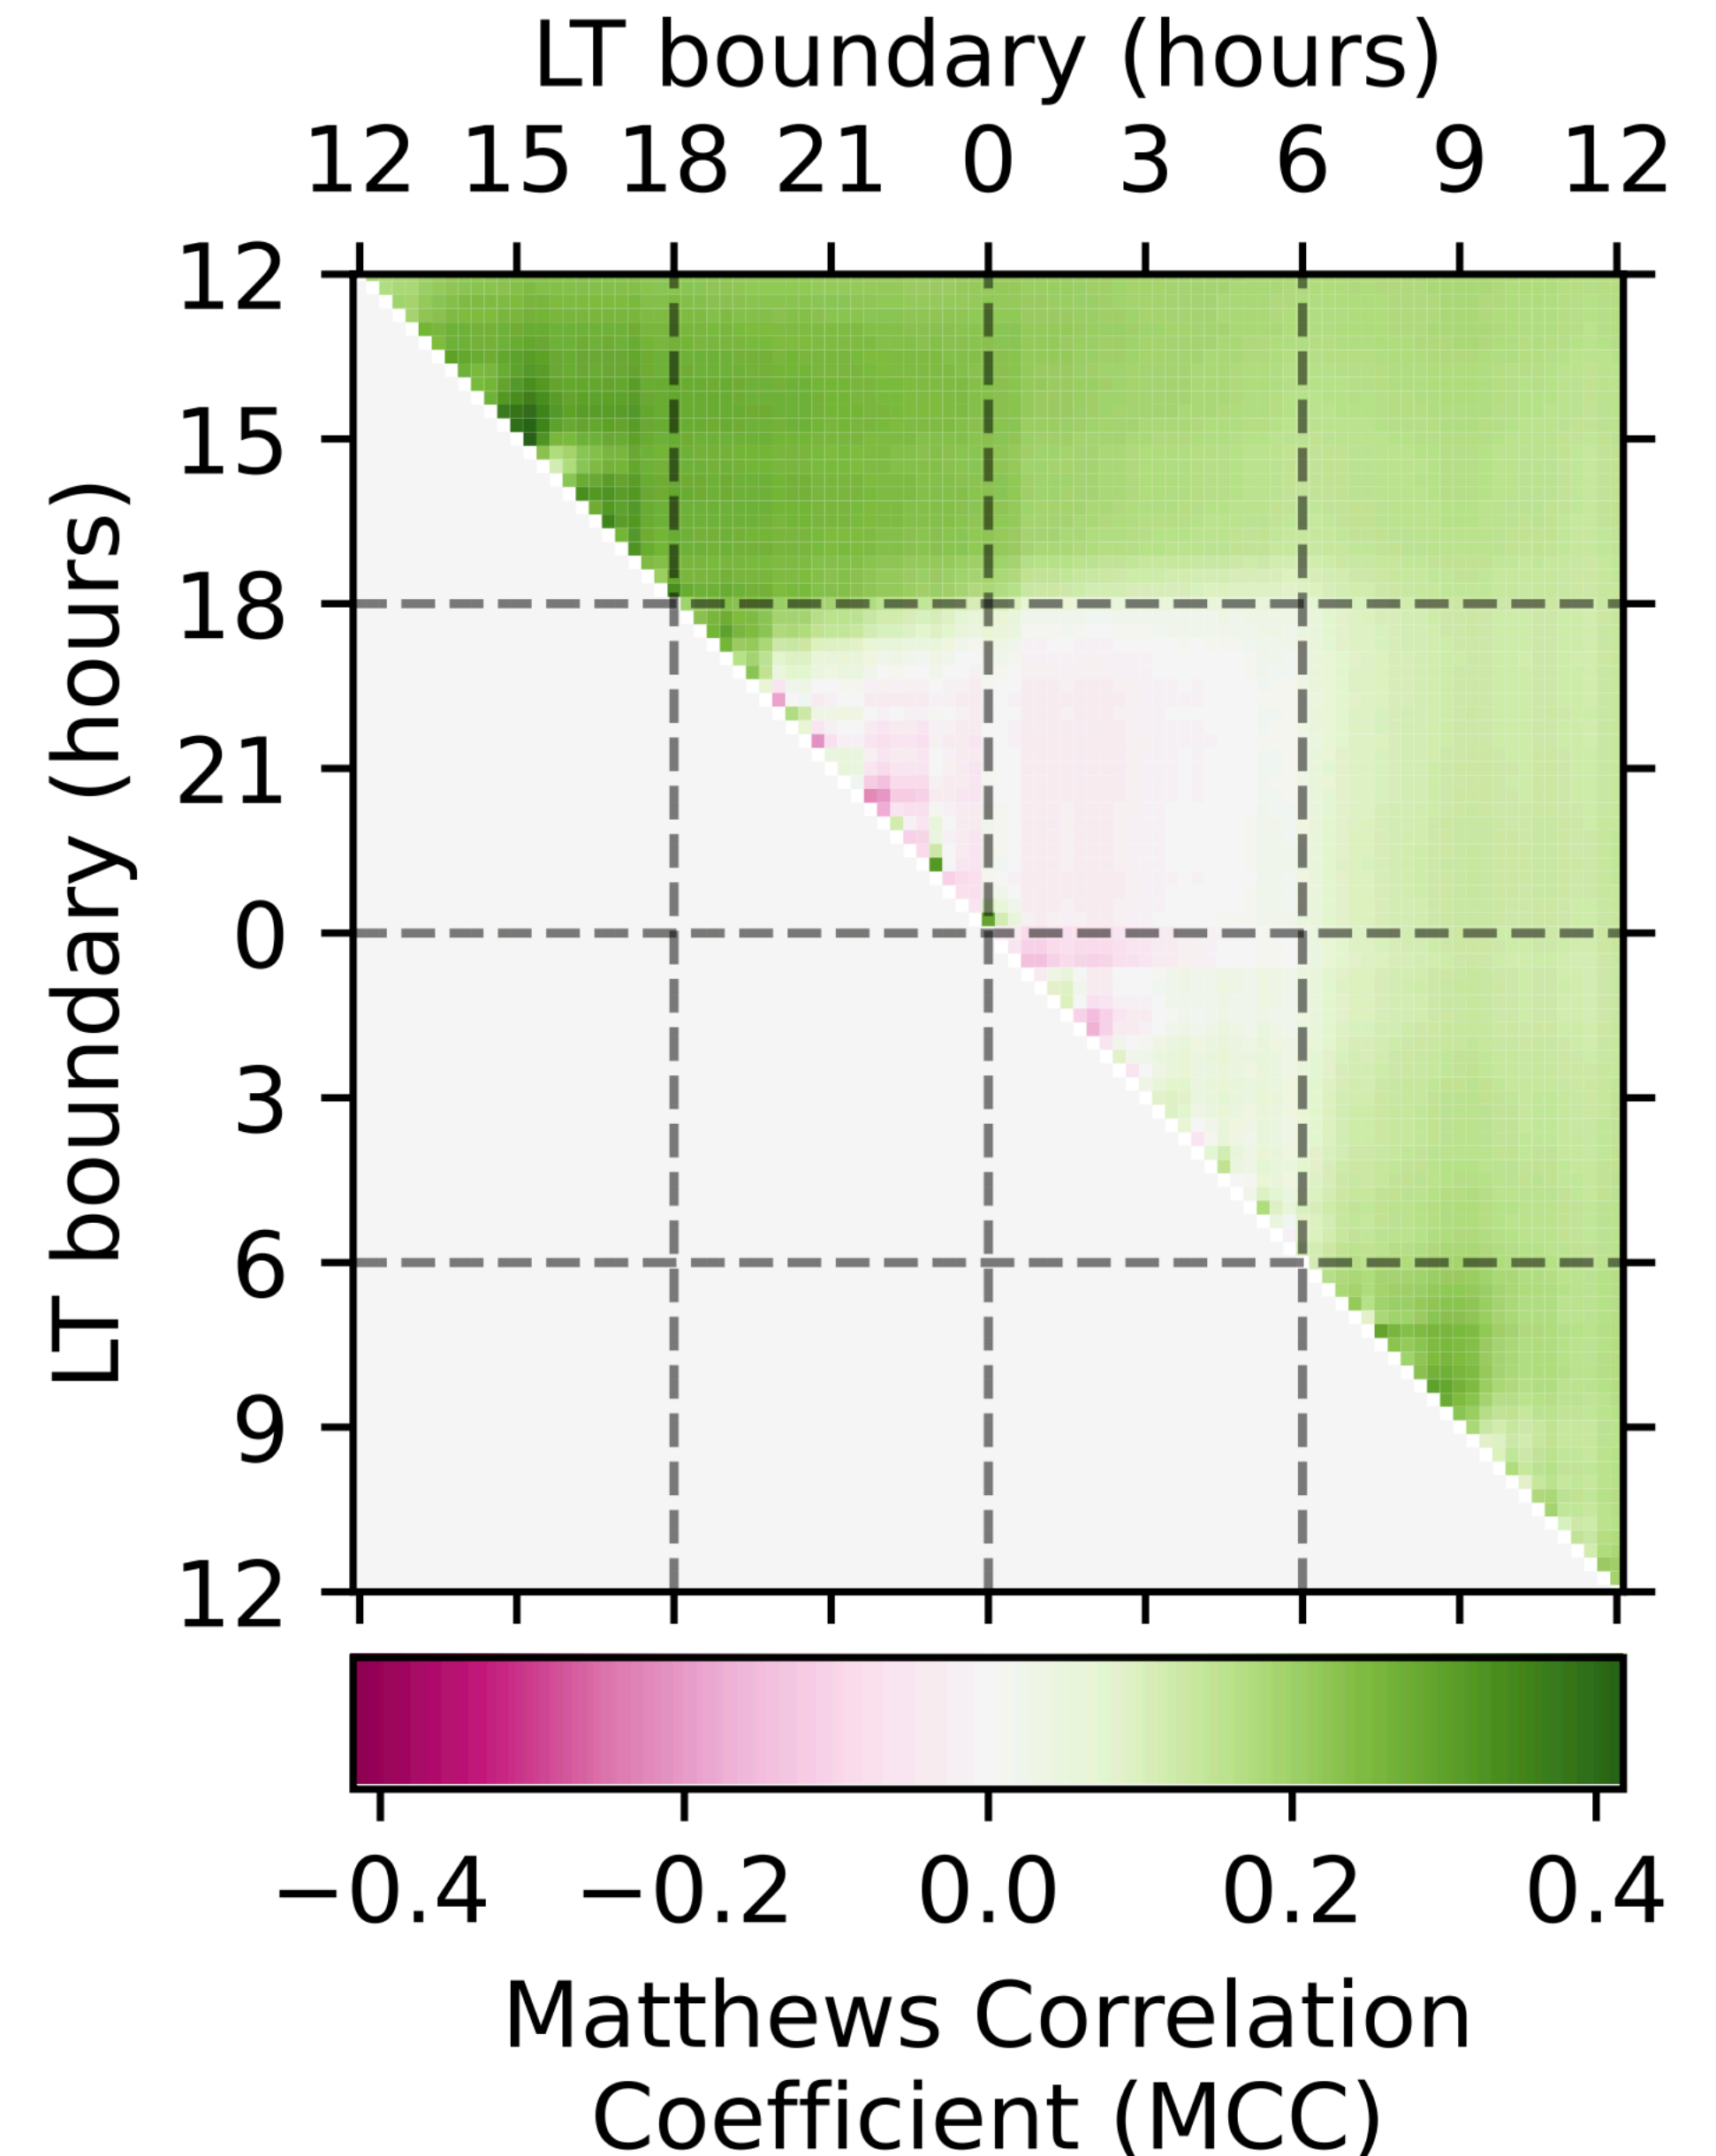

Binary classification of substorms with remote AKR observations

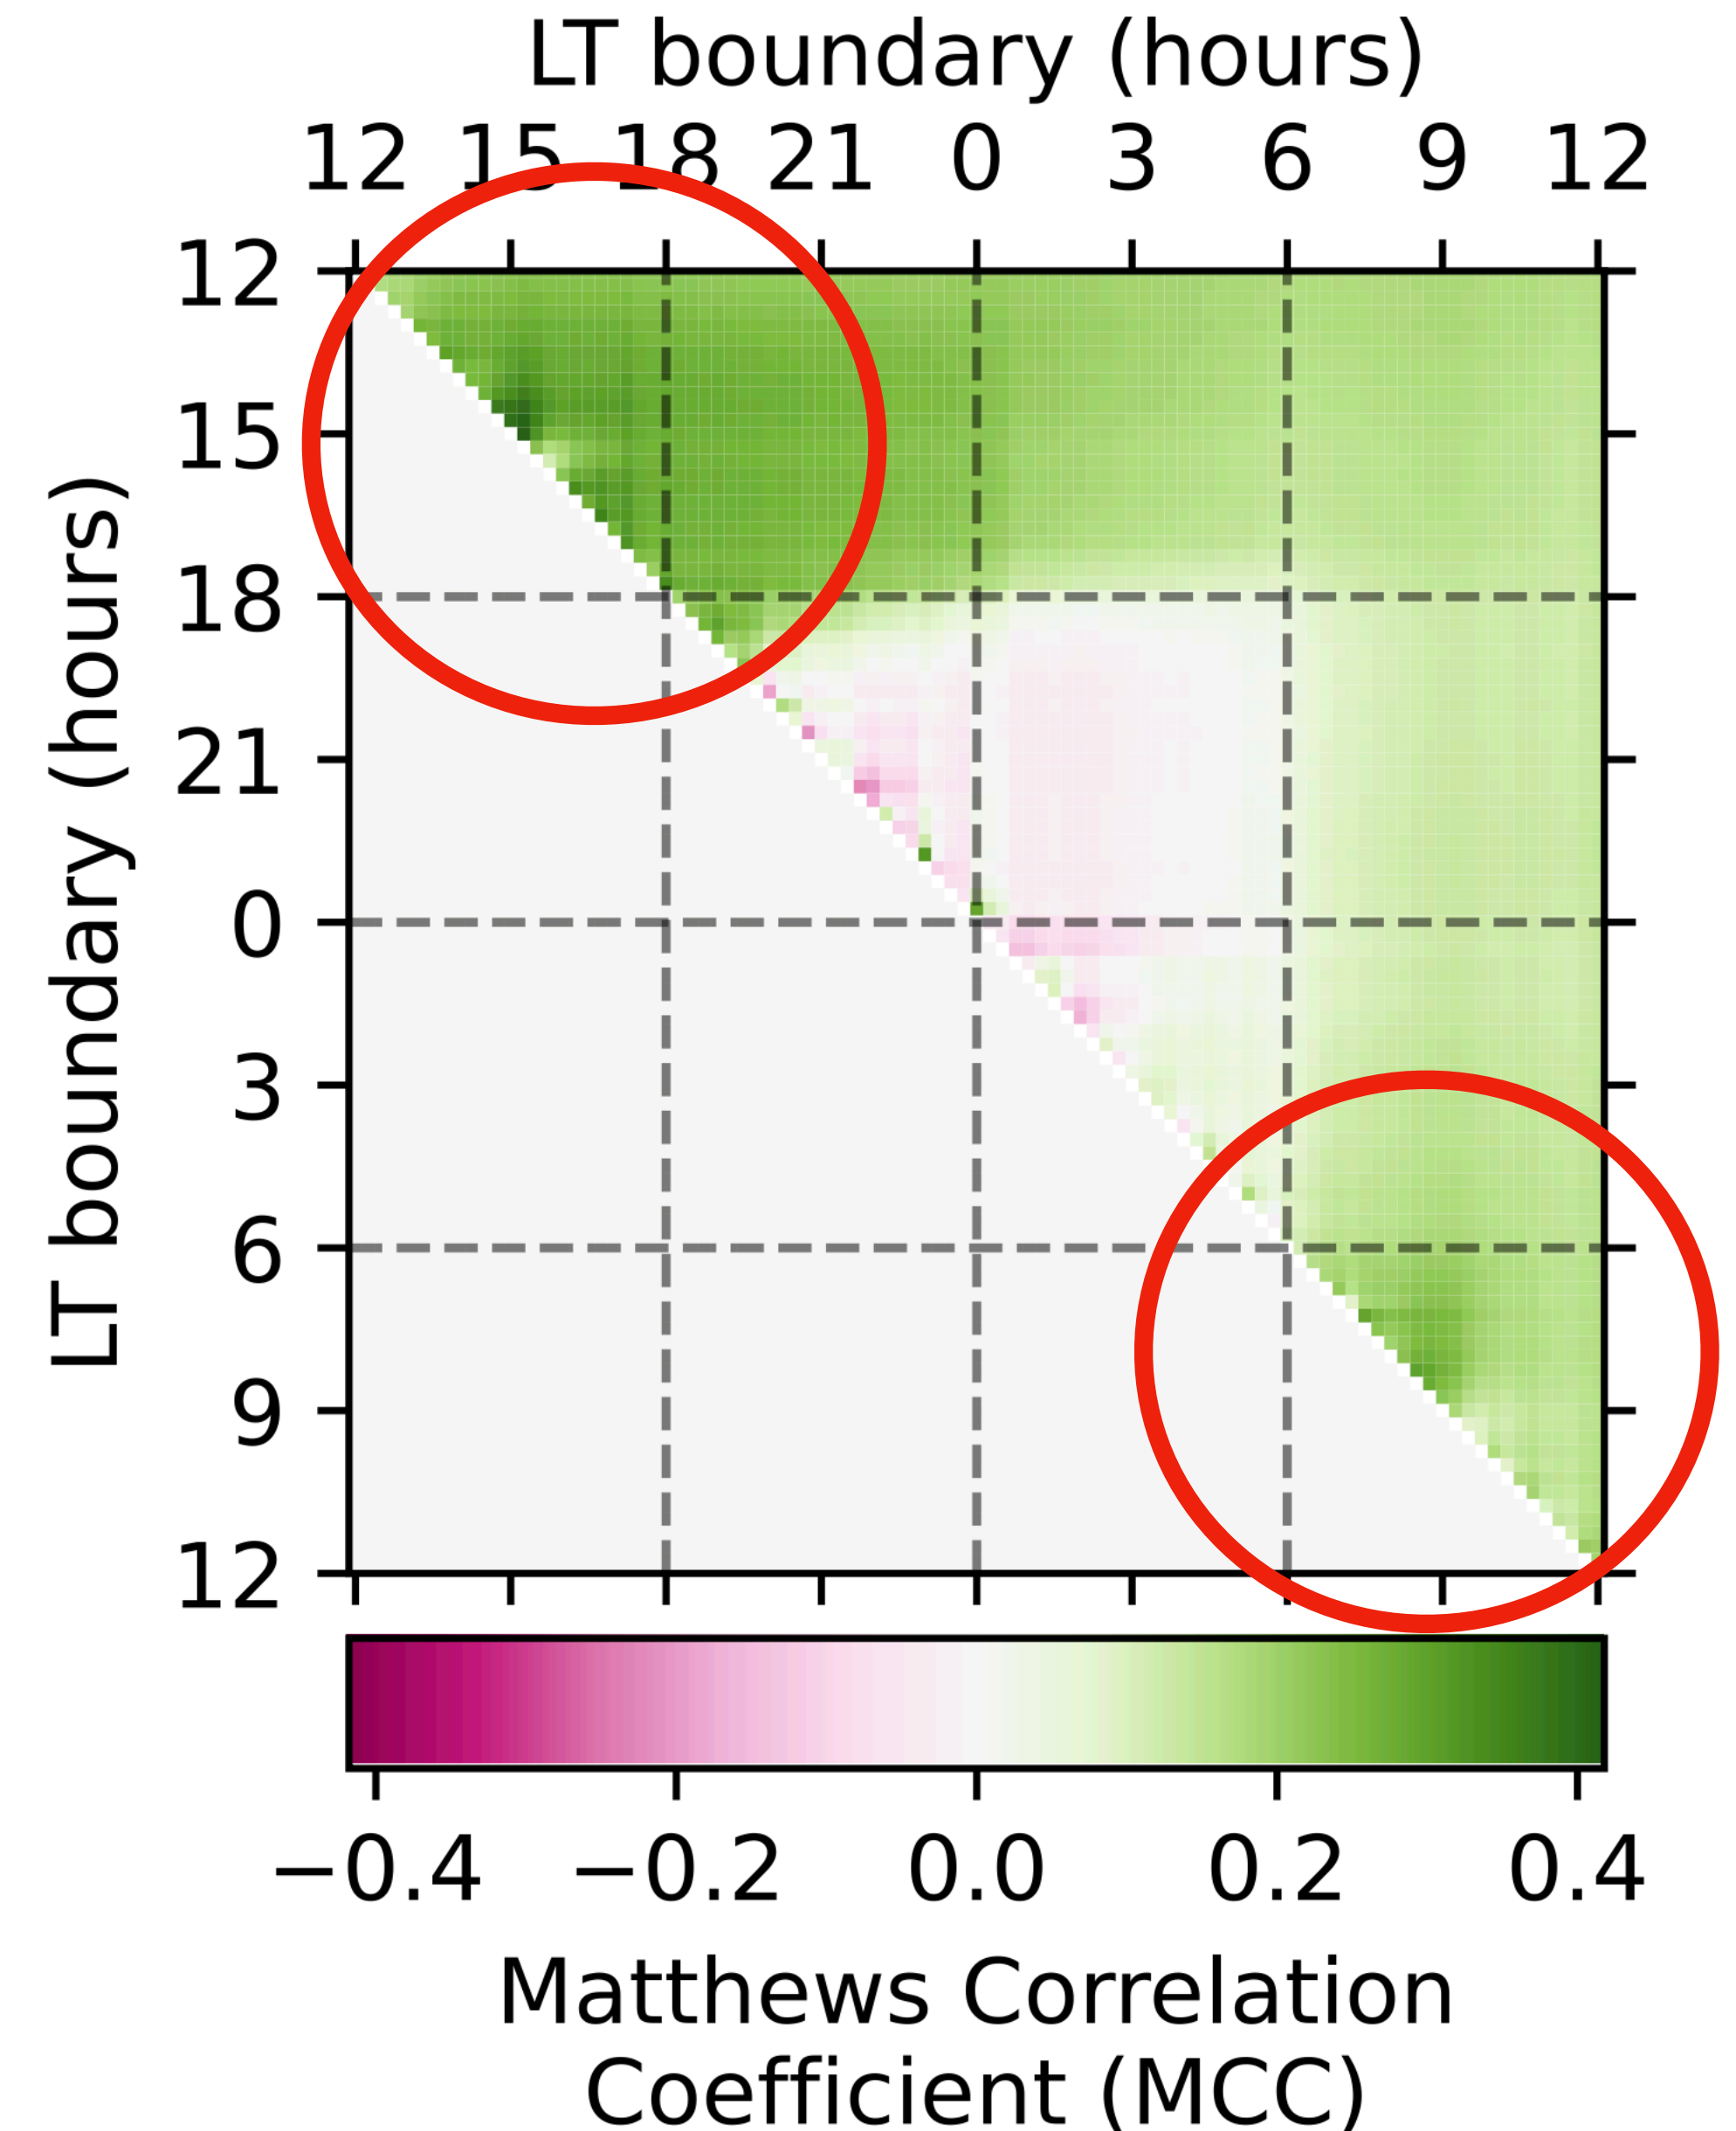

Binary classification of substorms with remote AKR observations

- Extend analysis to examine correlations of all LT sectors, varying widths
- Compute Matthews Correlation Coefficient (MCC) over all combinations of LT sectors from widths of 15 minutes
 - Observations at all duskside local times correlate positively (12-24 hrs LT)
 - Highest-skilled dawnside observations are more constrained made between 06-10 hrs LT

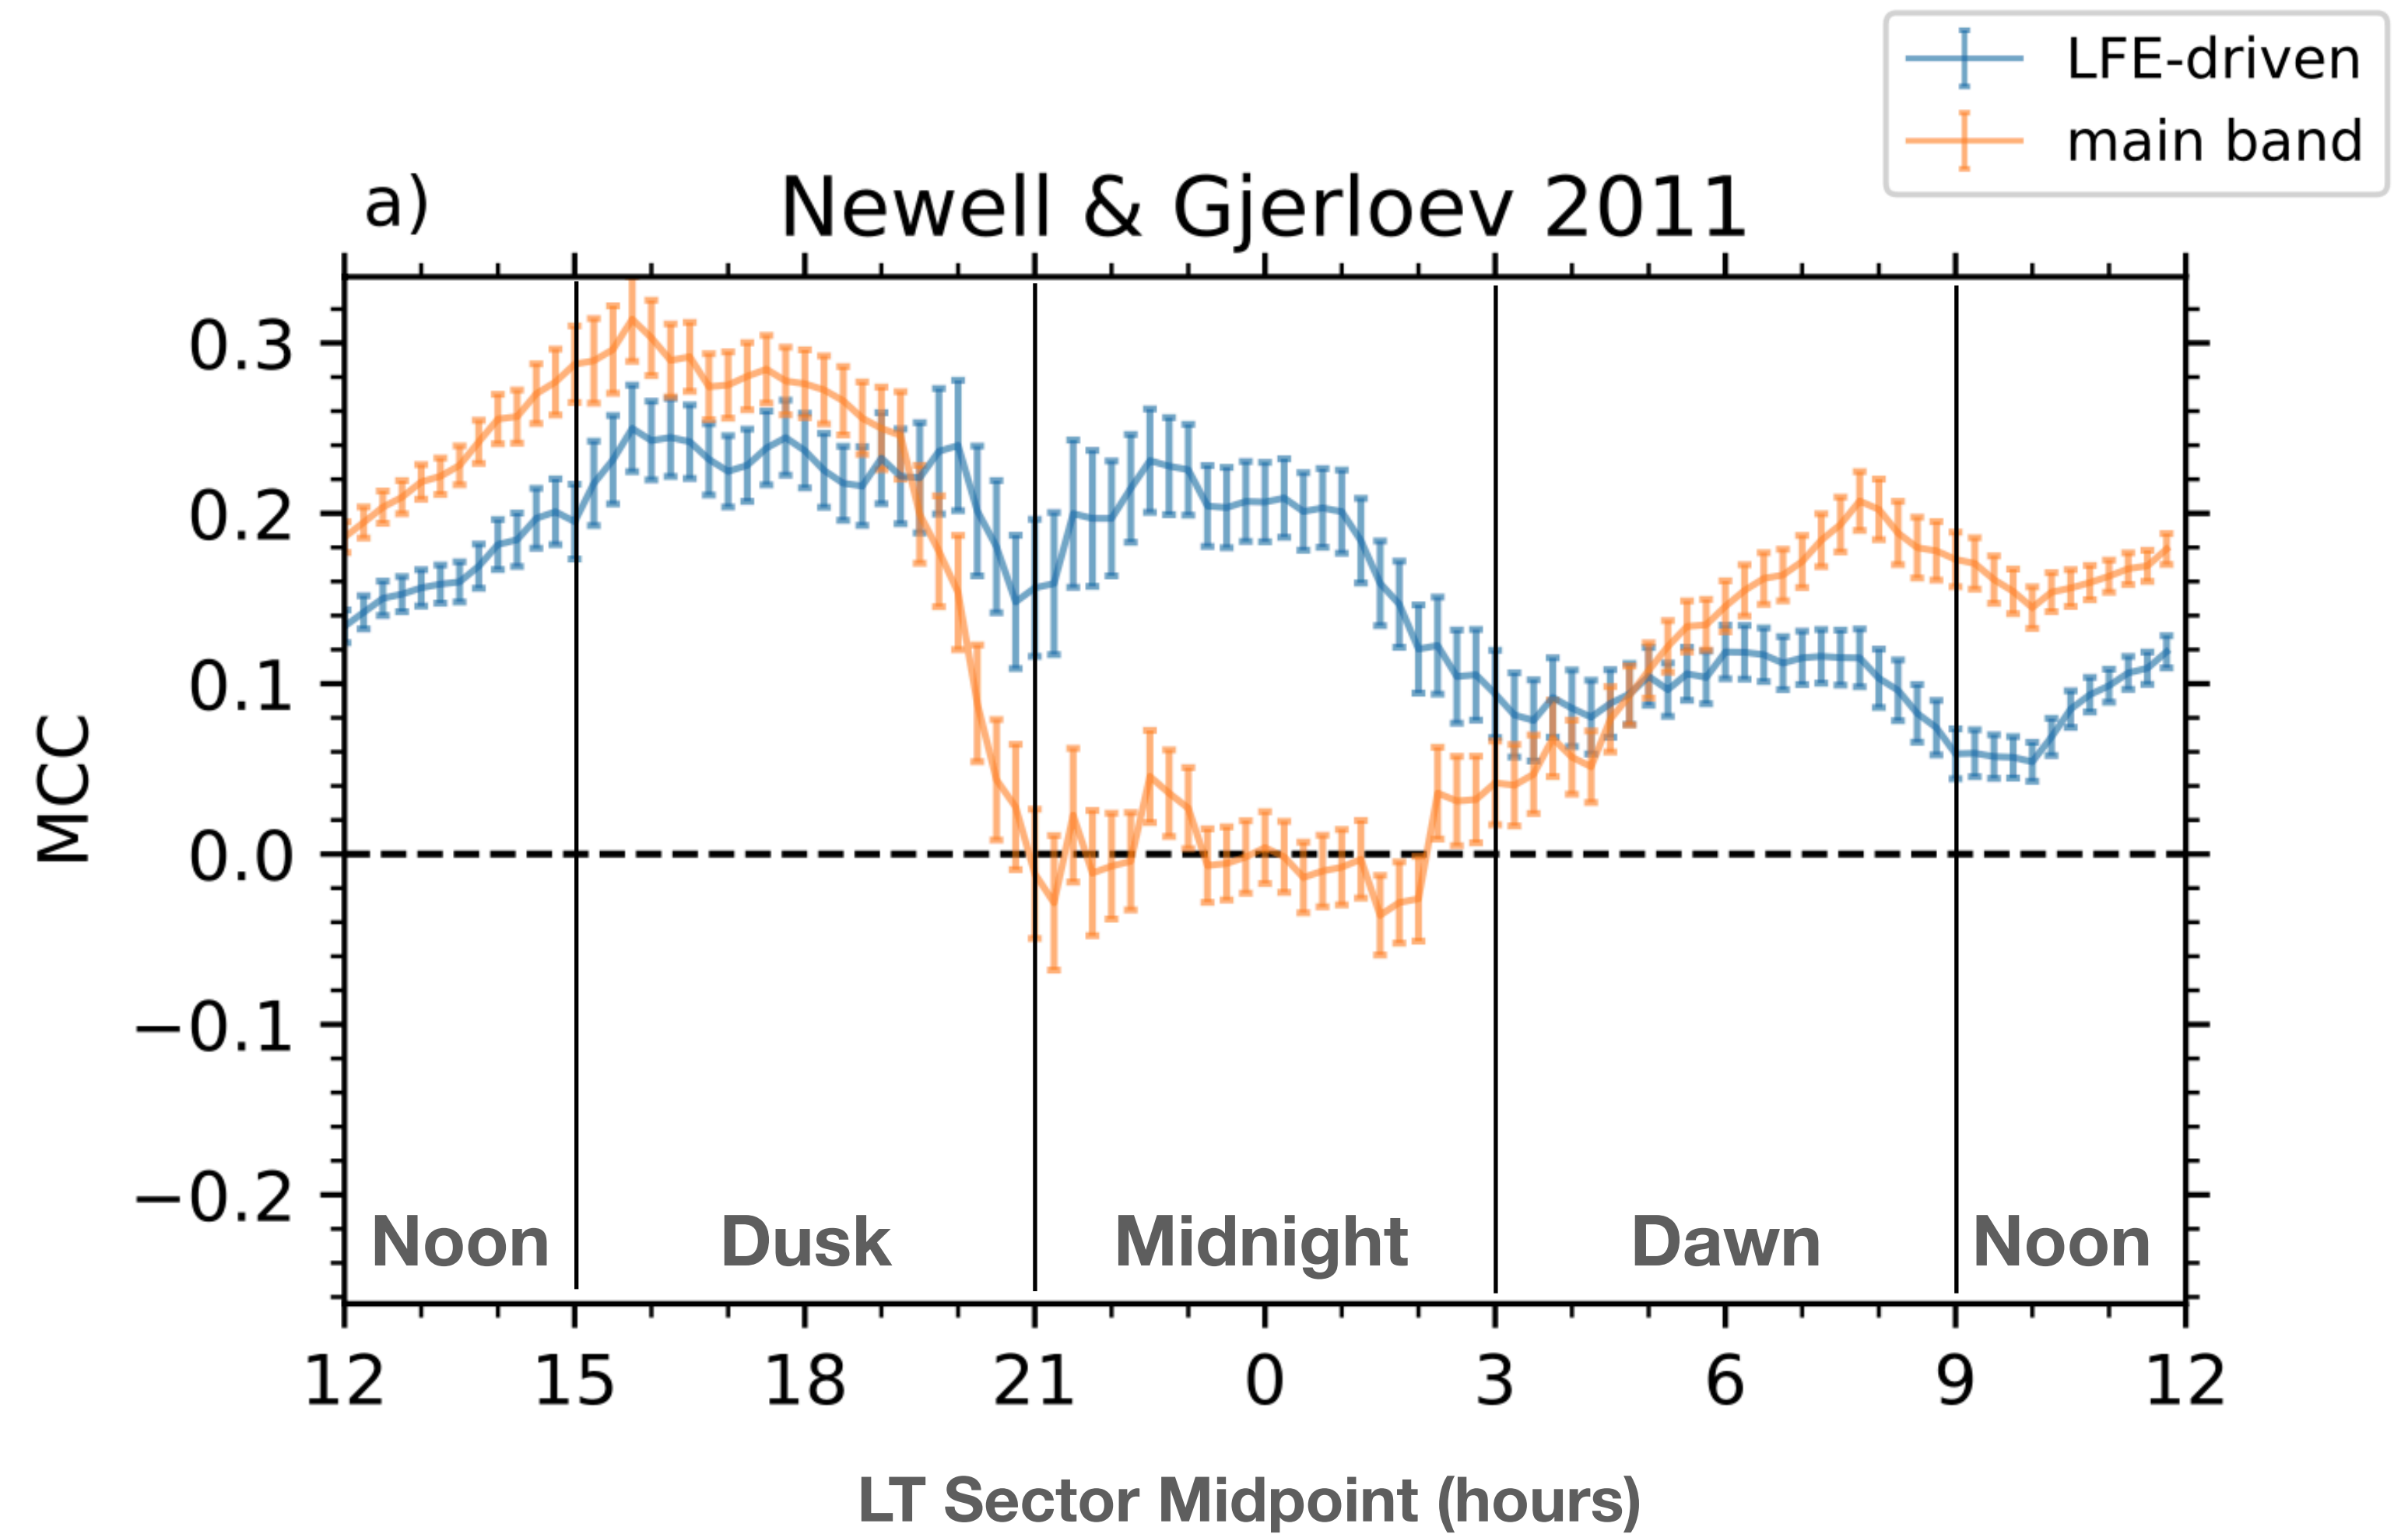

Binary classification of substorms with remote AKR observations

- Extend analysis to examine correlations of all LT sectors
- Compute Matthews Correlation Coefficient (MCC) over all combinations of LT sectors from widths of 15 minutes
 - Observations at all duskside local times correlate positively (12-24 hrs LT)
 - Highest-skilled dawnside observations are more constrained made between 06-10 hrs LT

Binary classification with frequency cutoffs

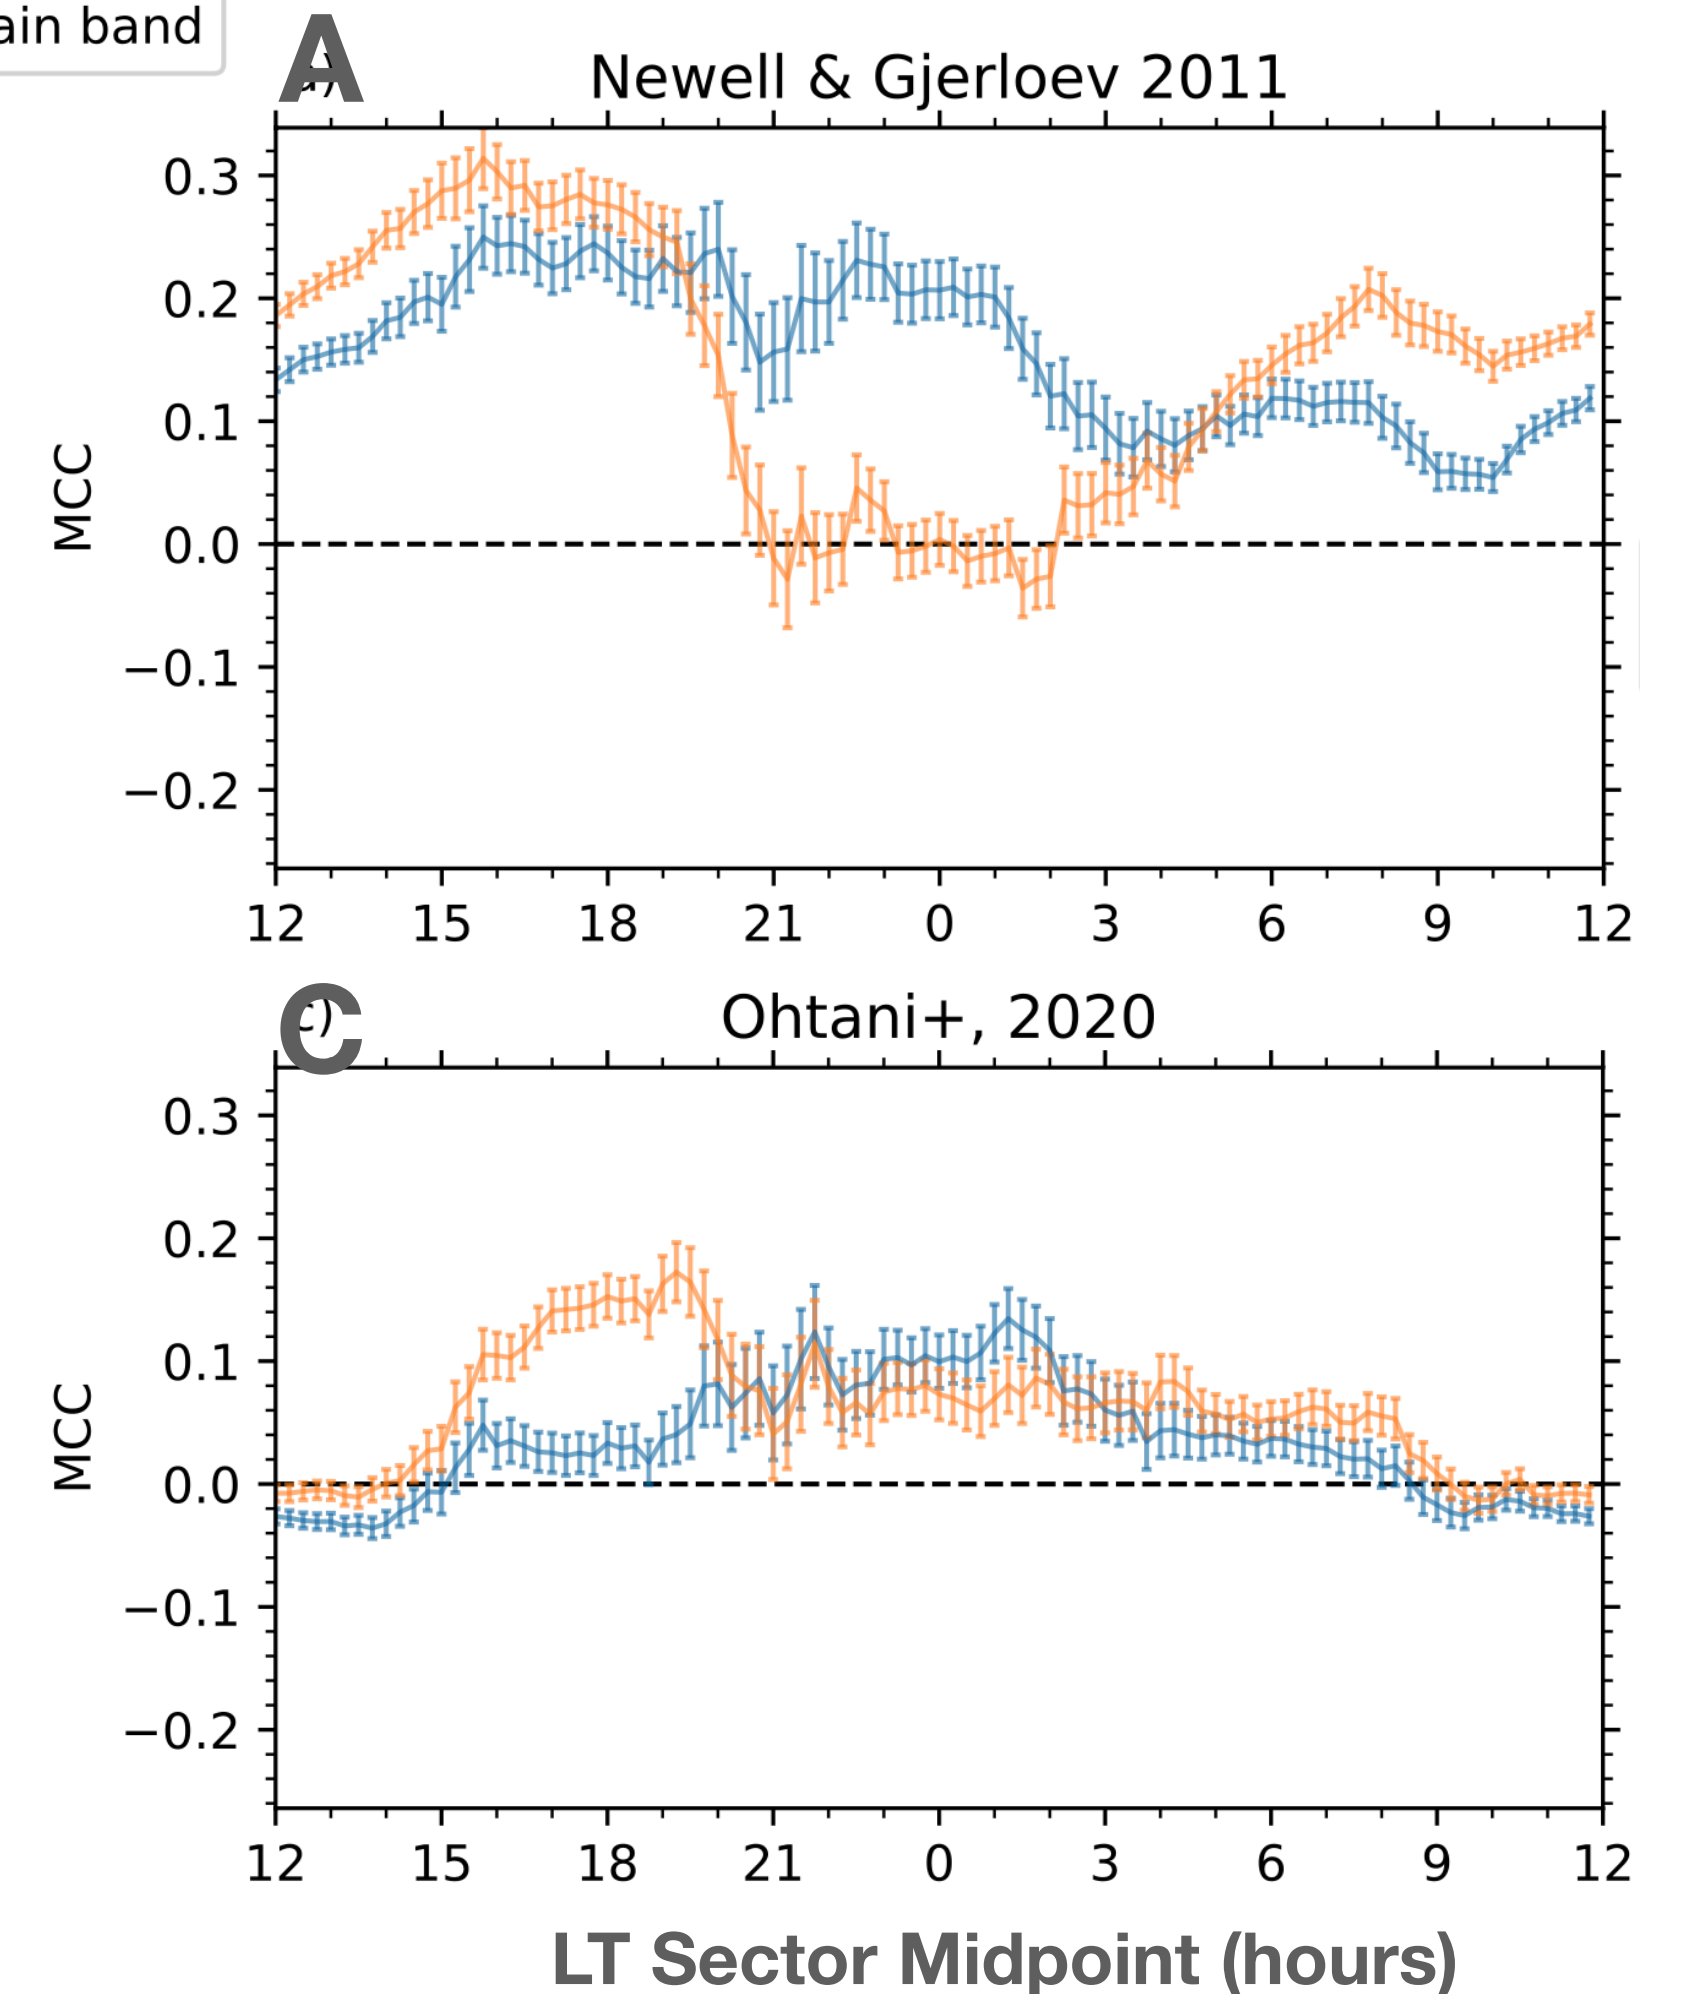

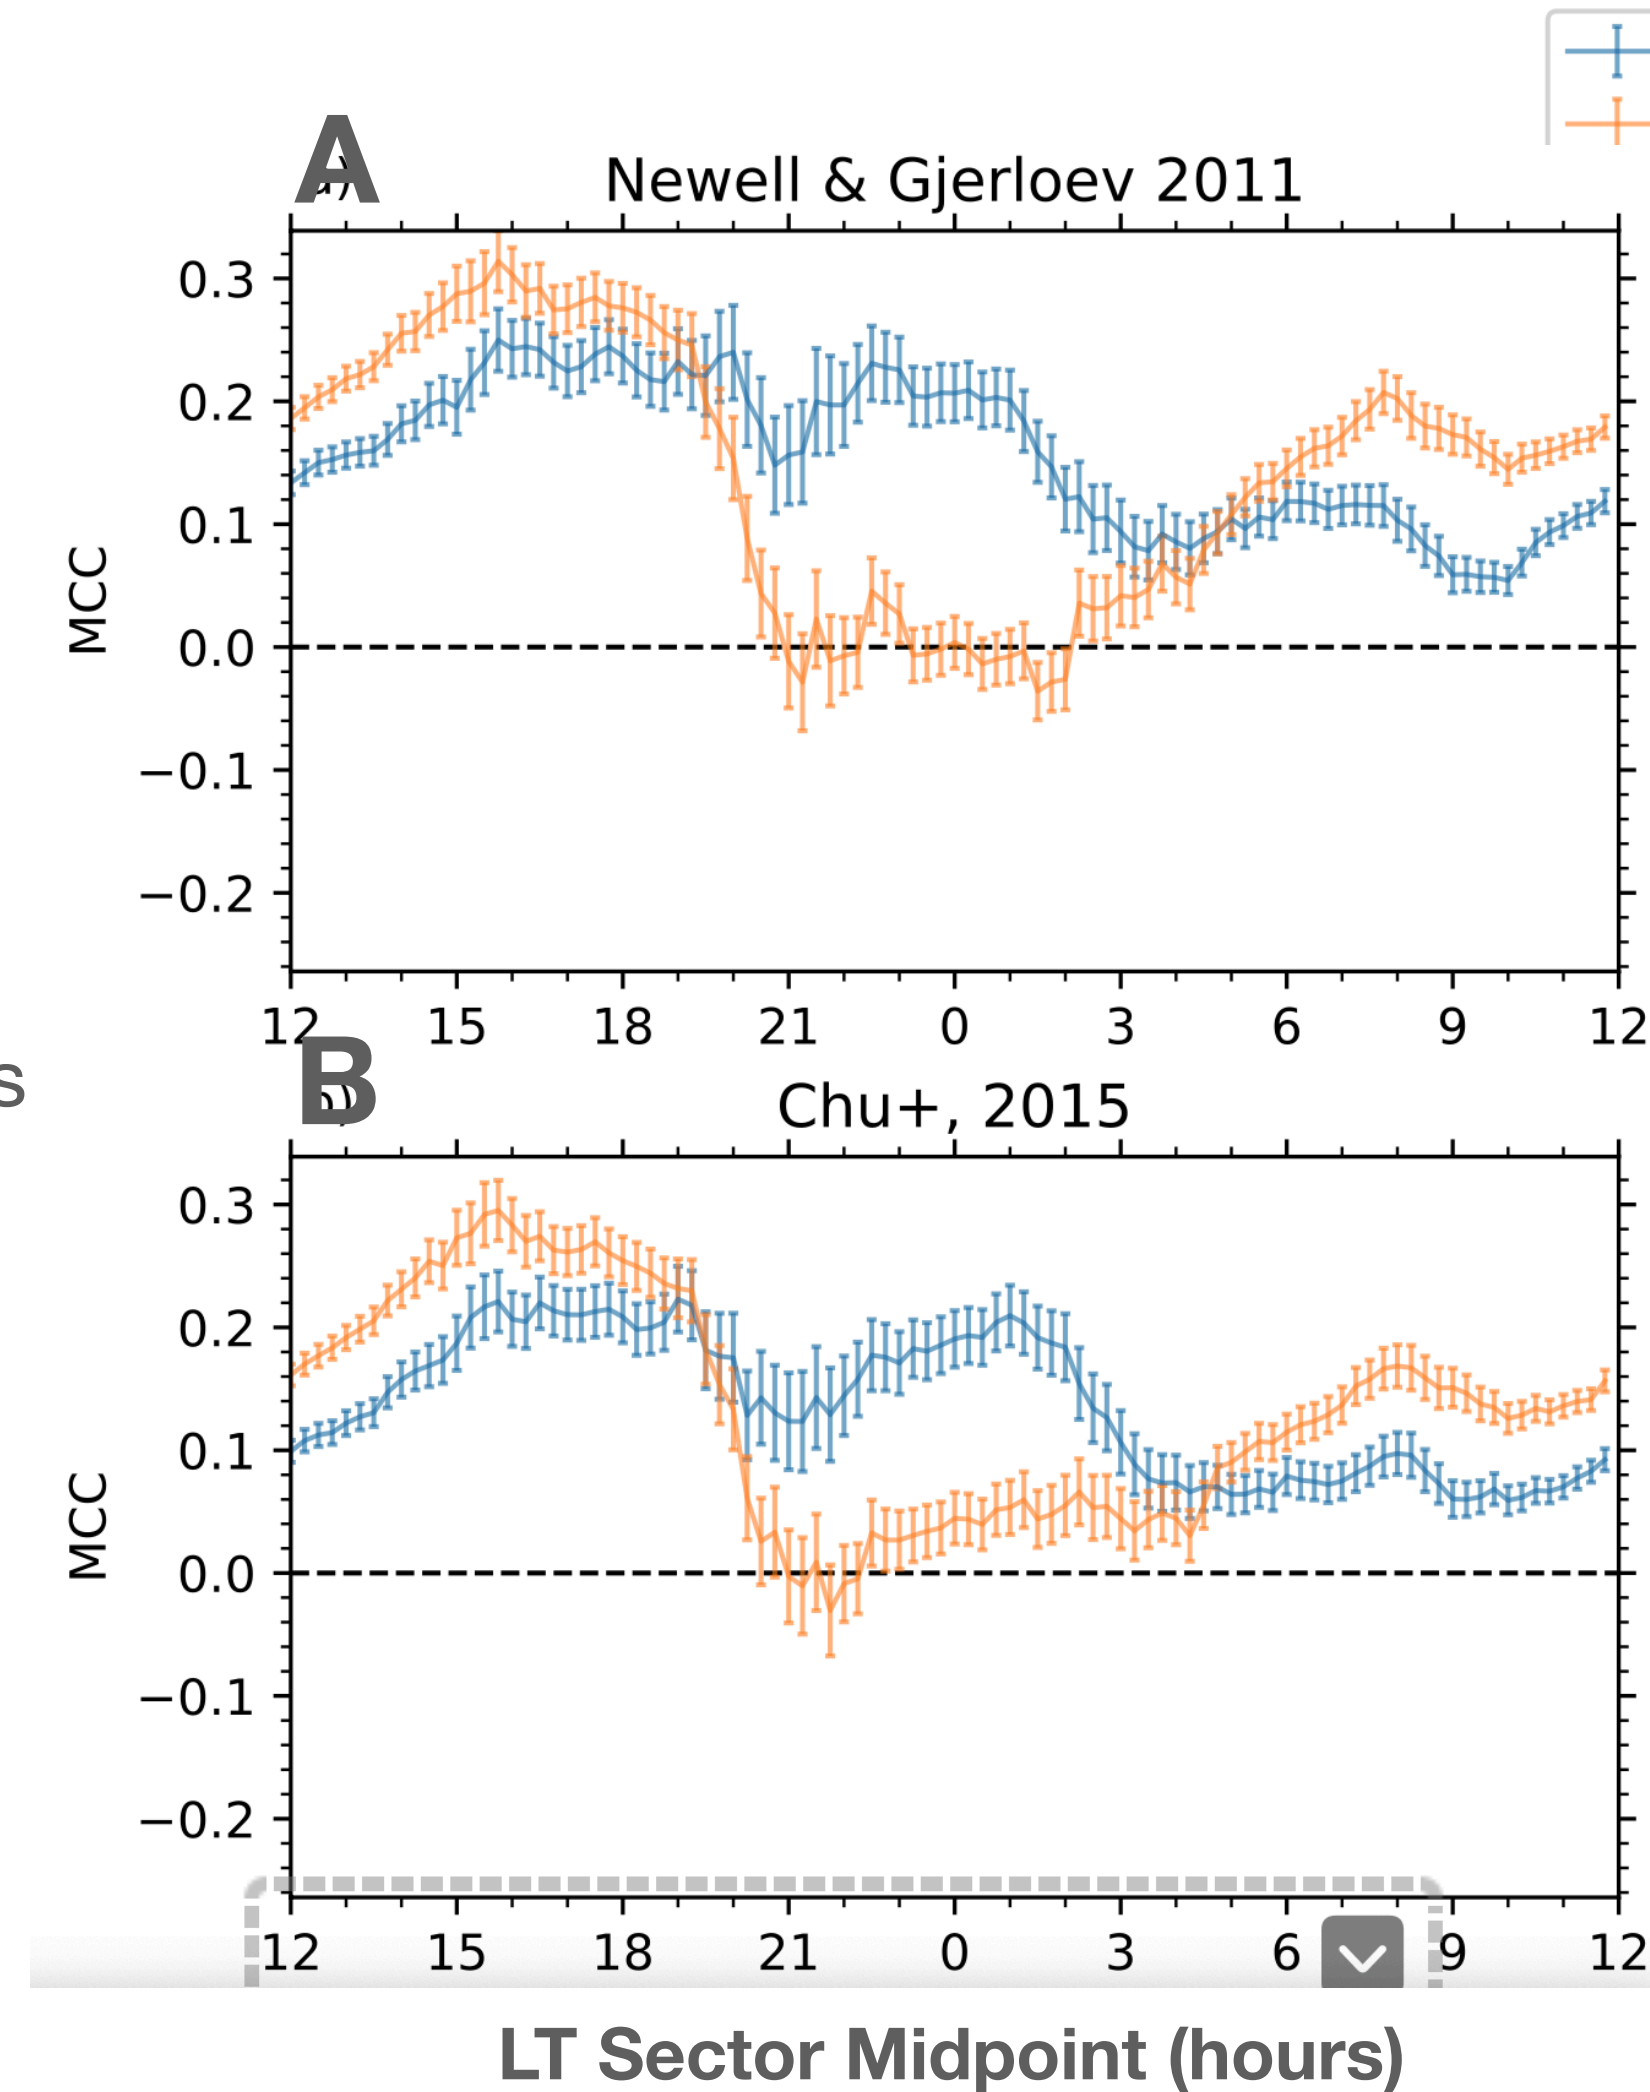

- Applying upper frequency cutoff to AKR burst occurrence
- Characterise “main band” and lower frequency AKR

Waters+ 2025

Binary classification with frequency cutoffs

- Panels showing different substorm lists - those shown based on substorm current proxies
- Lists A and B (multiple onset substorms included) have high correlations for dusk, dawn, daysides
- List C (isolated onsets with spatial constraints) constrained correlation on duskside
- Lower frequencies produce greater correlation at midnight, highlighting specificity to substorms

Waters+ 2025

Summary

- AKR occurrence correlates higher with substorm lists when observed from the dusk and dawn flanks, or near noon
- Midnight AKR observations have slightly negative correlation - low specificity from distribution of discrete aurora (*or diffuse? See S. Wu's poster E1*)
- Dayside observations have higher correlations for substorms with large spatial extension in aurora - can characterise events
- Lower frequency AKR increases correlation at midnight LTs
- These results:
 - Highlight discrepancies between substorm lists
 - Help determine auroral phenomena producing AKR with remote observations
 - Can be used to distinguish substorms with wide longitudinal distribution of aurora
 - Could help to model AKR source distribution for ionospheric auroral phenomena
